Incubated with H$_2$O$_2$ (10^{-4} M)	41·7
MnCl$_2$ omitted and incubated with H$_2$O$_2$ (10^{-4} M)	40·8
DPNH replaced by 'related' compounds† (2 mg) and incubated with H$_2$O$_2$ (10^{-4} M)	2·5
^{14}C-œstradiol substituted for œstrone (5 h incubation)	29·4
^{14}C-diethylstilbœstrol substituted for œstrone	31·0
Incubated with uterine 'oxidase-peroxidase' preparation (5 mg)	0·8

* Incubation mixture: peroxidase, 10 μg, œstrone, 10 μg, MnCl$_2$, 10^{-4} M; DPNH, 5×10^{-4} M, in 5 ml. Conditions as described in text.

† DPN, TPN, ATP, RNA, DNA, nicotinamide, adenine, guanine, thymine, cytosine, uracil.

No changes occurred under anaerobic conditions or if the peroxidase solution was boiled, and catalase was found to be strongly inhibitory, suggesting that hydrogen peroxide is involved in the reaction. In addition, the lower yield of water-soluble products obtained when the incubations were carried out in the absence of manganese could be restored by the addition of hydrogen peroxide (10^{-4} M). It appears, therefore, that horseradish peroxidase acting as an aerobic oxidase can utilize DPNH or TPNH to generate hydrogen peroxide and that afterwards, behaving like a true peroxidase, it can convert œstrone to metabolites which are either water-soluble themselves or capable of combining with the pyridine nucleotides. However, DPN or TPN could not replace DPNH or TPNH in the reaction in the presence of added hydrogen peroxide, and this finding deserves further investigation. A number of other compounds having features in common with the nucleotides (see footnote to Table 1) were tested but none had any effect.

Only when water-soluble products were formed could compounds other than the added œstrogen be detected in the ether extracts and these were all found to be more polar than œstrone and, with the exception of one compound, more polar than œstradiol-17β. Very little, if any, of this last steroid was formed.

Similar incubations with a lyophilized preparation (5 mg) of œstrogen-stimulated rat uteri, which in the presence of manganese and 2,4-dichlorophenol was shown to have high DPNH oxidase activity, did not result in the formation of water-soluble products from œstrone. In addition, this material did not give a positive reaction[6] with guaiacol, which suggests that the oxidase and peroxidase activities of œstrogen-stimulated rat uteri may be separate in contrast to horseradish peroxidase where both functions appear to be intimately connected. Hollander and Stephens[7] found that these two enzymatic activities were lost from uterine homogenates at different rates on storage, but their results indicate that the oxidase was more labile than the peroxidase.

Finally, it should be mentioned that the results with horseradish peroxidase are not in conflict with those obtained by Williams-Ashman *et al.*[8], who managed to recover virtually all their added œstradiol unchanged after incubation under similar conditions, since their experiments were of relatively short duration.

We thank Drs. V. P. and N. Hollander for a gift of rat uterine DPNH oxidase and Prof. R. L. Noble and the National Cancer Institute of Canada for their interest and support of this work.

Interference by Ammonium Sulphate with the Estimation of Proteins by the Biuret Reaction

THE procedure of Gornall, Bardawill and David[1] is widely used for the estimation of proteins, the only frequent modification being adjustment of the volumes to permit mixing of reagents and reading of the extinction directly in the cells of a spectrophotometer. Gornall, Bardawill and David[1] state that 'ammonium ion is a disturbing factor in the biuret reaction', but provide no quantitative data. Some information on the interference has been provided by Henry, Sobel and Berkman[2]; but these workers used two biuret reagents of different composition and instead of a pure protein used serum as a standard. The extent of the interference of ammonium ion with the biuret reaction does not appear to be widely known. Thus, Dixon and Webb[3] claim that "few of the non-protein materials likely to be present affect the estimation, and it is particularly useful because it is insensitive to ammonium salts".

Crystalline egg albumin (Sigma Chemical Co., St. Louis 18, Mo.) was dissolved in 0·15 M sodium chloride to a concentration of 10 mg/ml. Biuret reagent was prepared according to Gornall, Bardawill and David[1]. Protein solution (0·2 ml.), freshly filtered, saturated (20°–22°) ammonium sulphate and sufficient 0·15 M sodium chloride to bring the volume to 1·5 ml. were mixed and 1·5 ml. biuret reagent was added. The mixtures stood for 30 min at 20–22°. The extinction at 540 mμ was determined in a Shimadzu *QR* 50 spectrophotometer, using a blank consisting of 1·5 ml. 0·15 M sodium chloride and 1·5 ml. biuret reagent. The extinction values for duplicate tests with constant protein content and varying final concentrations of ammonium sulphate are shown in Table 1.

Table 1

Concentration of ammonium sulphate in final reaction mixture* as Per cent saturation	 Molarity	Extinction at 540 mμ of duplicate tests
0	0	0·191, 0·190
1	0·04	0·192, 0·191
2	0·08	0·185, 0·185
3	0·12	0·175, 0·175
4	0·16	0·151, 0·150
5	0·20	0·030, 0·028
6	0·24	0·033, 0·030

* 2 mg of protein per test.

It is clear from the results in Table 1 that a concentration of 0·08 M ammonium sulphate in the final reaction mixture already interferes appreciably with the recovery of protein, even though the level of protein selected for the tests was near the upper limit of the range in which extinction at 540 mμ is linearly related to the concentration of protein.

Composition of Normal and Pathological Cutaneous Elastin

ELASTIN, a fibrous protein invariably associated with collagen[1,2], has been quantitatively measured in a variety of mammalian tissues[3,4]. The amino-acid composition of elastin prepared from various animal sources including aorta[5], lung[6] and ligamentum nuchæ[7] has been reported and the elastin content of human dermis has been determined[8,9]. The purpose of this work was to determine the amino-acid composition of human dermal elastin and compare it with that of the elastin-like proteins found in increased amounts in chronically sun-damaged skin (actinic elastosis) and pseudoxanthoma elasticum[8].

Human skin was obtained at necropsy from two Caucasian adults. Actinic elastotic skin was removed under local anæsthesia from the forearm of two volunteers with a Brown dermatome (obtained from Dr. C. C. Tindall, Kissimmee, Florida). Pseudoxanthoma elasticum skin was obtained from a 46-year-old White female who died of a cerebral vascular accident with progressive deterioration (obtained from Dr. S. Polt, Duke University Medical Center). All hair was carefully removed by shaving and subcutaneous fat trimmed away. Skin specimens were frozen in liquid nitrogen, ground in a Wiley mill, and extracted three times with 0·1 N sodium hydroxide in boiling water bath for 15 min[8]. Between the first and second extractions the skin specimens were ground in a glass homogenizer. The suspensions were centrifuged at 20,000*g* and the residues air-dried on filter paper after washing with acetone and ether. Aliquots were desiccated in a vacuum oven for 3 h and then *in vacuo* over phosphorus pentoxide at 110° C for dry-weight determination. Duplicate aliquots of pathological elastin were hydrolysed under nitrogen for 24 h at 110° C with redistilled 6 N hydrochloric acid. Duplicate aliquots of control samples were hydrolysed *in vacuo* at 110° with redistilled 6 N hydrochloric acid for 24, 48 and 72 h. All amino-acid analyses were carried out on a Spinco model 120 automatic amino-acid analyser. Total nitrogen was determined by micro-Kjeldahl as well as by combustion; total ash was determined by combustion (performed in the Galbraith Laboratory, Knoxville, Tennessee). Amide nitrogen was determined after hydrolysis at 100° and atmospheric pressure for 2 h, with N hydrochloric acid followed by steam distillation and titration.

Table 1. AMINO-ACID COMPOSITION OF HUMAN DERMAL ELASTIN

Amino-acid	g Amino-acid/ 100 g protein	g Amino-acid residue/100 g protein	Nitrogen as as percentage of total

Aspartic acid	3·8	15	12	8
Glutamic acid	23·5	54	55	31
Hydroxyproline †	10·5	10·5	10·5	12
Amide	13·4	—	—	—

Amino-acid composition of normal and pathological human dermal elastins. Elastotic and pseudoxanthoma elasticum values are average of two samples. Controls represent best or extrapolated values from 24-, 48- and 72-h duplicate hydrolysis.

* Analysis reported by Partridge and Davis (ref. 7).

† Performed separately by the method of Neuman and Logan (ref. 13).

Kjeldahl nitrogen on a dry-weight basis gave 16·20 and 16·70 per cent for two control samples. Total nitrogen by combustion gave 16·04, 16·20 and 16·08; 16·04 on duplicate samples of two control specimens. Ash was 3·32 and 3·28 per cent respectively. Amino-acid analyses in all instances gave 95 per cent or better nitrogen recovery by weight of material put on the analyser; typical results are presented in Table 1. Table 2 summarizes the results and compares these results with published analyses on bovine ligamentum nuchae elastin[7].

The identity of the abnormally increased dermal fibres stained by classic elastic tissue stains in actinic elastosis and pseudoxanthoma elasticum has been the subject of considerable controversy[1,2,10]. The non-extractable collagen (insoluble collagen) in actinic elastosis has reduced amounts of proline and hydroxyproline relative to nitrogen suggesting that it is degraded[11]. In pseudoxanthoma elasticum, however, there is a slight reduction in the total collagen, but no evidence for degradation[12]. The fibrous proteins isolated in this work by hot alkali extraction of normal human skin and human skin involved with actinic elastosis and pseudoxanthoma elasticum have quite similar amino-acid compositions. These amino-acid compositions are also quite similar to elastins from other sources prepared differently. Based on solubility characteristics, amino-acid composition and elastase susceptibility[8,12] it seems unlikely that the elastin-like proteins found in actinic elastosis and pseudoxanthoma elasticum are derived from collagen.

Glucuronide Formation and Transport of Various Compounds by Gunn Rat Intestine *in vitro*

THE ability of the mucosa of the gastrointestinal tract to form glucuronides has been previously reported[1-3]. The function of such conjugate formation in the intestinal mucosa has not yet been clarified. It has been variously suggested that glucuronide formation by this tissue may play an important part in detoxification[3], in mucopolysaccharide formation[4], or in the absorption of various substances from the intestinal lumen[5,6]. A genetically determined deficiency of the enzyme responsible for the transfer of glucuronic acid from uridine diphosphate glucuronic acid (UDPGA) to various acceptors has been detected in the livers of homozygous Gunn rats[7,8]. The work reported here was undertaken to determine whether there is a similar deficiency of this enzyme (UDP transglucuronylase) in the intestine of the Gunn rat. The results provide further evidence for the similarity between

glucuronide synthesis in the intestinal mucosa and liver[3] and for the importance of glucuronide formation in the transport of various substances by rat intestine *in vitro*.

Various preparations of mucosa from normal and Gunn rats were examined for their ability to form glucuronides of *O*-aminophenol and of 4-methylumbelliferone. Male Wistar and homozygous Gunn rats weighing 100–120 g were fed until they were killed by decapitation. The small intestinal mucosa was stripped by scraping and 75–150 mg of tissue was incubated with either 0·2 μM of 4-methyl umbelliferone or 0·55 μM of *O*-aminophenol (in 0·01 M ascorbic acid) for 60 min at 37·5° C in 5 per cent carbon dioxide : 95 per cent oxygen. Whole homogenates and cell fractions of mucosa were prepared in 0·25 M sucrose and aliquots were incubated with the same two substrates for 40 min at 37·5° C in an atmosphere of nitrogen. 4-methyl umbelliferone glucuronide was estimated by a fluorometric technique[9] and *O*-aminophenol glucuronide by the method of Levvy and Storey[10]. The results are presented in Table 1. All the preparations from mucosa of Gunn rats had a markedly reduced ability to form glucuronides. Following homogenization of strippings of normal mucosa, glucuronide synthesis was reduced by about 85 per cent. An increased UDPGA requirement following homogenization probably results from hydrolysis of UDPGA by UDPGA pyrophosphatase[11]. Ethylenediamine tetraacetic acid was found to retard the hydrolysis of UDPGA as previously noted by Pogell and Leloir[12].

The active transfer of a number of substances from the mucosal to the serosal surface of everted sacs of rat intestine has been shown to be dependent on glucuronide conjugation[5,6,13]. With a number of thyroxine analogues, such as triiodothyroacetic acid (TRIAC), an ethereal glucuronide is formed, and all the radioactivity accumulating in the serosal medium is in the form of this conjugate[5]. With testosterone, the accumulation of radioactivity in the serosal medium results from the formation of a glucuronide of 3-α,17β-androstanediol[13]. In the case of the amino-acid L-monoiodotyrosine (MIT), 5–30 per cent of the radioactivity in the serosal medium can be recovered as an ethereal glucuronide of MIT. It has been suggested that the formation of a labile *N*-glucuronide may also be involved in the transport of this amino-acid although no direct evidence of such conjugation has been obtained[5,6]. The ability of sacs of Gunn rat intestine to transport these various substances has been examined to test further the hypothesis that their active transfer is dependent on glucuronide conjugation.

Everted sacs of normal and of Gunn rat intestine were incubated with TRIAC, MIT, or testosterone as previously described[5,6,13]. Glucuronide production was estimated following separation by paper chromatography (using secondary butanol/ammonia (150 : 50) for TRIAC and MIT and Bush B_1 solvent system for testosterone). The results are presented in Table 2. Using both TRIAC and testosterone, the final ratio of radioactivity in the serosal medium to that in the mucosal medium of sacs from Gunn rats was less than 50 per cent of normal. With MIT, on the other hand, the concentration gradients were consistently greater with sacs from Gunn rats although the quantity of phenolic glucuronide of MIT which could be detected in these sacs was less than normal. These results do not resolve the question of whether the formation of labile *N*-glucuronides is involved in the transport of amino-acids, since the ability of Gunn rats to form *N*-glucuronides has recently been shown to be normal[14].

These investigations provide support for the view that the biosynthesis of glucuronides in intestinal mucosa is similar to that in liver. They also provide further evidence that glucuronide formation plays a major part in the active transfer of thyroxine analogues and certain steroids by the mucosal cell.

Solvent-Induced Changes in the Absorbancy of Isolated Chloroplast Fragments

IN a previous paper[1], we described changes in absorbancy which occur when leaves of green plants are subjected to certain alcoholic or acetonic treatments. In order to obtain further evidence as to the nature and possible significance of these changes in absorbancy, this work has been extended to a treatment of isolated chloroplast fragments.

Chloroplasts were prepared from leaves of *Nicotiana tabacum* (Habana 38) according to the method described by Arnon *et al.*[2]. The final pellet containing the 'purified' chloroplasts was then suspended in 0·05 M phosphate buffer at *p*H 6·7, precipitated by centrifugation, and resuspended in the same buffer. The resulting suspension was checked by microscopic examination to ascertain a low starch and debris contamination. Such preparations gave essentially the same response to alcoholic treatment after as long as 12 days' storage at 2 to 4° C. Absorbancy measurements were made in a recording Beckman *DK*-2 spectrophotometer at room temperature. The absorb-

* 5×10^{-4} M cupric chloride.

† Absorbancies multiplied by the dilution factor so that values are directly comparable with preceding measurements. Ethanol added following the 75-min treatment.

ancies were corrected for light scattering as previously described[1].

When redistilled methanol is added to a chloroplast preparation at room temperature to a concentration of 65 per cent (v/v), results such as shown in Fig. 1 are obtained. After a short lag, the main absorbancy band of chlorophyll in the red region decreases within 1 h to a value often representing as little as 15–20 per cent of the original peak absorbancy. Results of a similar experiment are shown in Table 1. After about 30 per cent of the absorbancy of the chlorophyll in the red region has been lost, a new absorbancy maximum at a wave-length near 740 mμ begins to appear. At the completion of this reaction, as much as 30 per cent to 50 per cent of the original chlorophyll absorbancy has thus shifted. None of these changes is observed with methanol concentrations above 80 or below 60 per cent. Similar results are obtained with ethanol at a concentration of 52 per cent. The rate of appearance and amount of 740-mμ absorbing material formed is affected by *p*H. At *p*H 5 or below little 740 mμ absorbing material is formed, while a *p*H of about 8·5 appears optimum.

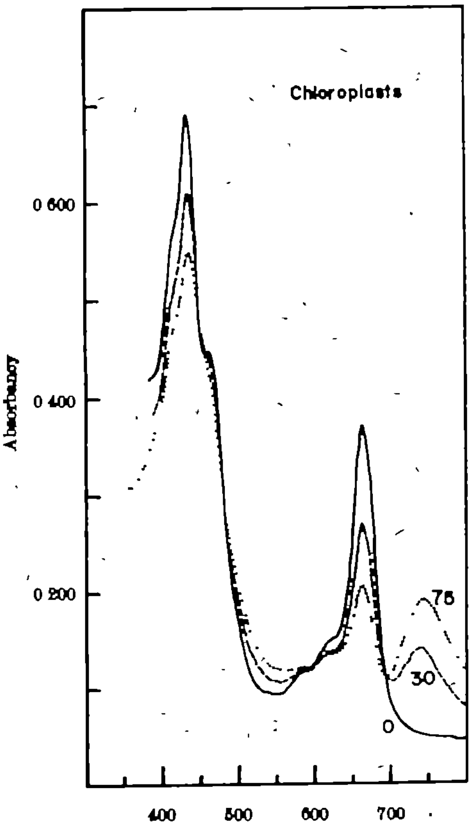

Fig. 1. Changes in absorbancy as a function of time when isolated chloroplast fragments are suspended in 65 per cent methanol: solid line, absorbancy immediately after addition of methanol; dashed line, 30 min after addition; dotted line, 75 min after addition

At methanol concentrations between 70 and 75 per cent a similar loss in chlorophyll absorbancy near 662 mμ is observed but without the formation of a 740 mμ absorbancy maximum (Table 1). At these concentrations of methanol, the absorbancy of the chlorophyll is shifted from about 678 mμ in buffer alone to 662–663 mμ in the presence of the alcohol. At 65 per cent methanol, where a 740-mμ maximum is formed, the chlorophyll absorbancy maximum is shifted to only about 670 mμ. Since the absorbancy of chlorophyll at these higher wave-lengths is due to its binding in the plastid structure[3], these results indicate that the changes resulting in the formation of the 740 mμ absorbancy maximum proceed without completely extracting the chlorophyll from its natural environment.

The validity of this conclusion was demonstrated in the following way. Chloroplast fragments were suspended in 75 per cent methanol and allowed to bleach (Table 1). These mixtures were then centrifuged at 2,500*g* for 15 min and the precipitate suspended in 65 per cent methanol. The addition of ethanol to the supernatant and to a portion of the resuspended precipitate indicated that most of the 'bleached' chlorophyll precipitated with the chloroplast fragments and was, therefore, still in a bound form. The material in the precipitate, however, on resuspension in 65 per cent methanol gives rise to a 740 mμ absorbancy maximum. Thus, chlorophyll remains bound to portions of the chloroplast structure at higher alcohol concentrations than those which are required to produce the 740 mμ absorbancy maximum.

The loss in chlorophyll absorbancy when these chloroplast fragments are suspended in 75 per cent methanol may be as great as 80 per cent of the initial value and is completely reversible. The reversal may be accomplished by increasing the concentration of the organic solvent which brought about the bleaching or by extracting the chlorophyll with any suitable solvent. Since no 740-mμ absorbing material is formed under these conditions, these results demonstrate that a bleached form of chlorophyll is being formed in these mixtures and is reversed by the addition of more solvent. If, following such a treatment in which the chlorophyll absorbancy first disappears and then reappears, the mixture is rediluted with water to an appropriate solvent concentration, the formation of the bleached form of chlorophyll proceeds anew.

An additional change in chloroplast fragments treated with alcohol under these conditions is observed on microscopic examination of the material. By doing particle counts on equal dilutions of these preparations and estimating the size of the particle examined, it is possible to show that the chloroplast fragments from non-treated preparations are three to four times larger than those receiving alcoholic treatment. Such a result is consistent with the requirements for obtaining a crystallization of the materials in these fragments as discussed in a previous paper[1].

Since the formation of a bleached form of chlorophyll appears to be either an oxidation or a reduction of the parent molecule[4], the ability to obtain such a change with a natural constituent of the chloroplast in the presence of methanol might be of considerable importance in the study of the initial stages of photosynthesis. This is true whether this change be mediated through enzymatic action or through direct chemical processes. Some evidence has been obtained which suggests that the formation of this bleached form of chlorophyll in these experiments may be an enzymatic process (Table 1). Chloroplast fragment preparations placed in a boiling water bath for 5–7 min do not show this loss in chlorophyll absorbancy or the formation of 740 mμ absorbing material. The initial chlorophyll absorbancy peak nevertheless shows a shift from 678 mμ to 670 mμ in response to the addition of 65 per cent methanol, just as it does in non-boiled samples. Cupric chloride, at a concentration of 5 × 10^{-3} M or higher, also inhibits the loss of chlorophyll absorbancy and prevents the appearance of material absorbing at 740 mμ. A similar concentration of this salt has been found necessary to inhibit the 'Hill reaction'[4]. No absorbancy changes occur when chloroplast–methanol mixtures are placed at – 26° C. Although the high concentration of alcohol necessary to obtain these changes appears to be very unphysiological, it should be recalled that at least two other enzymes attributed to the chloroplast require similar conditions for activity. They are phosphatidase c[5,6] and chlorophyllase[7].

These results provide conclusive evidence that the solvent-induced changes described in a previous paper are due to chlorophyll and fragments of the plastid structure. The decrease in size of these chloroplast fragments which accompanies the formation of the 740 mμ absorbancy maximum is consistent with the assumption that this change involves a crystallization of the chlorophyll molecules. A reversible bleaching of chlorophyll as a result of these treatments is clearly demonstrated in these investigations. The relation of this bleached form of chlorophyll to the formation of a 740 mμ absorbing band is such that the bleached form may be an intermediate. The effects of boiling, cupric chloride and low temperature suggests that an enzymatic reaction is responsible for the production of this bleaching.

This investigation was aided in part by a grant from the Jane Coffin Childs Memorial Fund for Medical Research.

Argininosuccinic Acid in Germinating Seeds of *Vicia faba* L.

THE ornithine cycle amino-acids have been determined in ungerminated seeds and 6- and 14-day-old seedlings of *Vicia faba* L. grown without an external source of nitrogen.

The amino-acids were identified by: (1) their elution characteristics from 'Zeo-Karb 225' (200–300 mesh, × 9 per cent); (2) their R_F values on two-dimensional paper chromatograms using 80 per cent (w/v) aqueous phenol as the first solvent and *n*-butanol/acetic acid/water (58 : 180 : 20 v/v/v) as the second; (3) colour tests for arginine[3]; argininosuccinic acid[4]; citrulline[5].

Argininosuccinic acid was separated from the free amino-acids of extracts of 500 g ungerminated beans using a 50 × 2·8 cm column of 'Zeo-Karb 225' (200–300 mesh, × 9 per cent), desalted by the method of Mueller[6] and identified using the following criteria.

(1) It was eluted from cation exchange resins as the anhydride forms and emerged as a discrete peak between leucine and tyrosine[7].

(2) Chromatography with 80 per cent (w/v) aqueous phenol gave two spots with ninhydrin, the R_F values of which, 0·27 and 0·47, corresponded to those of 'active' argininosuccinic acid and its anhydride respectively[4].

(3) The anhydride gave a colour in the Jaffe reaction[4].

(4) It behaved as a dicarboxylic amino-acid on paper electrophoretograms using *p*H 6·5 pyridine, acetic acid, water, buffer (10 : 0·4 : 90 v/v/v) and a potential of 12 V/cm (20 m.amp).

(5) It was acid stable, but on refluxing with strong barium hydroxide gave equal amounts of aspartic acid and ornithine[4].

Table 1. CHANGES IN MG NITROGEN IN THE ORNITHINE CYCLE AMINO-ACIDS OF 100 G FREEZE-DRIED UNGERMINATED BEANS, 6- AND 14-DAY-OLD SEEDLINGS OF *Vicia faba*

The amino-acids were determined colorimetrically (ref. 1) after separation on cation exchange resins under conditions similar to those used by Moore and Stein (ref. 2)

Amino-acid	0 days	6 days	14 days
Arginine	1,123	662·32	197·83
Argininosuccinic acid	2·46	6·53	78·84
Citrulline	0	0	62·71
Ornithine	0	0	31·69

In view of these findings, it is of interest that the enzyme argininosuccinase, which reversibly catalyses the formation of argininosuccinic acid from arginine and fumaric acid, has been shown to be present in peas[8], jack bean meal[9], and green pea, ryegrass and wheat[10]. The occurrence of argininosuccinic acid together with the other acids of the ornithine cycle strongly supports the previous suggestion that part, at least, of the ornithine cycle is involved in the metabolism of plants as well as animals.

When arginine labelled with carbon-14 was vacuum-infiltrated into disks of 10-day old cotyledon, subsequent extraction and chromatography of the free amino acids showed that argininosuccinic acid and proline were the first amino acids to become labelled. With increasing length of time of incubation of the tissue with ^{14}C-arginine, ornithine, citrulline, glutamic acid, aspartic acid and finally alanine and γ-aminobutyric acid, became radioactive. The importance of these amino acids in the metabolism of germinating seeds of *Vicia faba* L. will be discussed fully in a later publication.

Alteration of Steroid Dehydrogenase Synthesis in a Mutant of *Pseudomonas testosteroni*

Marcus and Talalay have described two nicotinamide-adenine dinucleotide (NAD) dependent steroid dehydrogenases obtained from induced culture of *Pseudomonas testosteroni* (American Type Culture Collection 11996)[1]. The α-enzyme catalyses the oxidation of 3α-hydroxy steroids while the β-enzyme reacts with the 3β- and 17β-hydroxy steroids. Extracts of the cells grown in the presence of testosterone exhibit both types of activities. The enzymes may be separated from one another by careful ammonium sulphate fractionation and can then be used as reagents for quantitative determination of their respective substrates.

A culture of the organism was obtained from the American Type Culture Collection in July 1958, and several lots of cells were prepared and assayed by the methods in the reference. Androsterone was used as the type substrate for α-activity, testosterone for β. (The reaction mixture contained 100 μmoles sodium pyrophosphate, *p*H 9·0, 0·5 μmole NAD, 15 μg steroid in 0·1 ml. methanol, 0·1 ml. cell extract in a total volume of 3·0 ml. The control cuvette contained all components except that 0·1 ml. methanol was substituted for the steroid. The reaction was initiated by addition of steroid. Absorbances were read at 30-sec intervals at 340 mμ in a Beckman *DU*.)

From October 1959 until April 1961 stock slants of the organism on basal medium plus testosterone were stored without transfer. When a transfer was made in April 1961 the growth was examined and found to be contaminated with other bacteria. The culture was plated out by dilution and the *Pseudomonas* isolated and recultivated in pure culture. When a batch of cells from this isolate was collected, dried, extracted and assayed for dehydrogenase activity, it was found that the cells were no longer active with testosterone while androsterone activity remained intact.

Repeated transfers of the organism produced cells which, when extracted, showed only the α-activity. After storage of these cultures on slants from April 1961 until October 1962, fresh transfers still produced the same enzyme pattern. Another culture obtained from the American Type Culture Collection in April 1961 and stored on agar slants has continued to yield both enzymes.

In testing, extracts of cells were prepared by grinding 100 mg dried cells with an equal weight of alumina and 5·0 ml. 0·03 M phosphate, *p*H 7·2, 0·001 M ethylenediamine tetraacetic acid. 0·1 ml. of such an extract when diluted 1–10 produced an absorbance change at 340 mμ of approximately 0·010–0·050/min with either steroid. The extracts from the altered cells, while always active on androsterone, never produced any change in absorbance with testosterone, even when undiluted. Extracts of fresh cells from slants showed the same behaviour as the dried cells.

It was concluded from the foregoing observations that a mutant strain had been formed in the contaminated culture which maintained its genetic marker for the lack of the β-activity. Its usefulness seemed apparent in the application of these enzymes as steroid reagents as expressed here.

However, further testing of extracts of the mutant cells, prepared as described here, revealed, to our surprise, distinct activity in dilutions of 1–25 with dehydroepiandrosterone (3β-hydroxy-Δ^5-androstene-17-one), producing an absorbance change of 0·020–0·030/min at 340 mμ. Repeated tests, under identical conditions, with testosterone as the substrate, failed to reveal any activity.

The chance contamination of the dehydroepiandrosterone was ruled out by purity determinations, including chromatography.

These results suggest that the mutant cells contain a β-steroid dehydrogenase, different from, and more highly specific than, that reported previously or that the earlier described β-steroid dehydrogenase contains two components, each specific for the 3β- and 17β-hydroxyl groups respectively. On the other hand, the explanation may be more complicated, for example, the mutant may produce a completely different enzyme such as an isomerase specific for the 3-position and the product may then be subject to the α-steroid dehydrogenase. Finally, there is the remote possibility of elaboration by the mutant of a factor inhibitory for the testosterone enzyme. These matters are presently under study.

We thank Mr. Nick Denny for culturing the cells and performing the isolation of the mutant.

Zinc Toxicity in Brewer's Yeast

Zinc toxicity is known to reduce the levels of the hæm enzymes cytochrome oxidase and catalase in the rat[1] and in the larvæ of the rice moth *Corcyra cephalonica*[2]. This communication reports observations made on cytochrome oxidase levels in and fermentation by *Saccharomyces carlsbergensis* after growth in media containing toxic concentrations of ionic zinc.

S. carlsbergensis was grown aerobically at 30° C in either Walters and Thistleton's medium[3] (control culture), or in this medium containing 450 μg/ml. zinc as the acetate ('zinc toxic' culture). Preliminary experiments in which growth results were determined turbidimetrically indicated that this concentration of zinc was sufficient to reduce the rate of growth by half. After 24-h incubation the yeast was centrifuged down, washed in and suspended in 5 vol. of de-ionized water.

Studies on oxygen uptake, and aerobic and anaerobic fermentation demonstrated that all three systems were affected by ionic zinc.

Table 1. OXYGEN UPTAKE AND FERMENTATION IN YEAST

	Normal culture	'Zinc toxic' culture
Oxygen uptake (μl. O_2/mg dry weight)*	27·8	16·5
Aerobic fermentation (μl. CO_2/h/mg dry weight)	63·4	28·4
Anaerobic fermentation (μl. CO_2/h/mg dry weight)	32·6	16·0

Manometer vessels contained 1 ml. yeast suspension plus 1 ml. 6 per cent (w/v) glucose in the main compartment, and 0·2 ml. 2 N potassium hydroxide in the centre well for oxygen uptake studies; for aerobic fermentation, potassium hydroxide was removed and replaced with 2 N sulphuric acid; for anaerobic fermentation, 0·1 ml. potassium cyanide was added to the yeast suspension.

* All figures are arithmetic means of levels in three separate cultures.

Cytochrome oxidase assays were performed on a cell-free extract of yeast obtained using a Hughes press. The results demonstrated a decreased level of the oxidase in zinc toxicity.

Table 2. CYTOCHROME OXIDASE LEVELS IN YEAST

	Cytochrome oxidase* (μl. O_2/h/mg protein (ref. 4))
Normal culture	32·1
'Zinc toxic' culture	15·1

Manometer flasks contained the following reaction mixture: 0·2 ml. 0·01 M diaminoethane tetraacetic acid, neutralized to *p*H 7·0 with sodium hydroxide, 0·2 ml. 7 × 10^{-4} M cytochrome *c*, and 0·2 ml. of yeast extract in the main compartment, and 0·2 ml. 5 per cent (w/v) sodium ascorbate in side-arm. The final volume was made to 2·0 ml. with 0·1 M *tris*, *p*H 7·3. Mixture was equilibrated for 10 min, contents mixed, and oxygen consumption measured over 25 min.

* All figures are arithmetic means of levels in three separate cultures.

This communication provides evidence that excessive zinc may interfere with the levels of hæm enzymes in plant as well as animal species.

PHYSIOLOGY

Influence of the Œstrous Cycle and Ovariectomy on the Phospholipid Content of the Pineal Gland in the Rat

AMONG the various roles attributed to the pineal gland in mammals the most important seems to be its influence on the function of the hypophysis and gonads. However, the results obtained by different investigators are contradictory[1]. In order to obtain some knowledge of the possible relationship between the pineal gland and the gonads, the histological and histochemical picture of the gland was examined during the œstrous cycle and following ovariectomy.

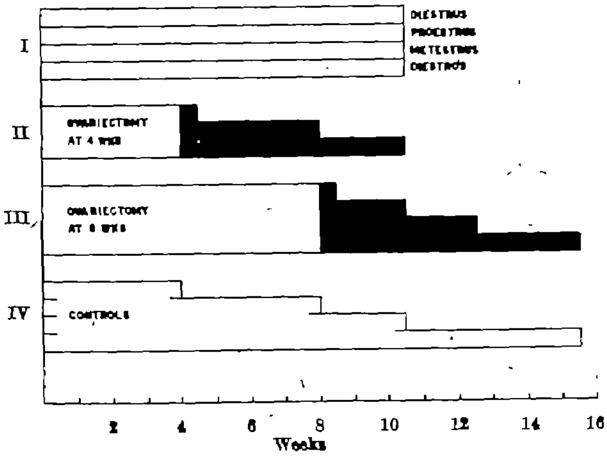

Fig. 1. Outline of the experiments; each bar represents six animals

In the experiments recorded here 4 series of virgin female rats were used (Fig. 1). In series I, 24 animals were killed at the age of 10·5 weeks in different phases of the œstrous cycle: 2 groups of 6 animals at di-œstrous, 6 at pro-œstrous and 6 at met-œstrous. In series II, 18 animals were ovariectomized at the age of 4 weeks and killed in groups of 6 rats each: the first group 3 days, the second 28 days, and the third 45 days after ovariectomy. In series III, 24 animals were ovariectomized at the age of 8 weeks and killed in 4 groups of 6 rats each: the first one 3 days, the second 17 days, the third 31 days and the fourth 52 days after ovariectomy. In series IV, 24 animals, serving as controls to series II and III, were killed at di-œstrous in groups of 6 rats each: the first group at the age of 4 weeks, the second 8 weeks old, the third 10·5 weeks old and the fourth 15·5 weeks old.

The pineal glands were stained with sudan black *B*, after previous controlled chromation[2]. This technique is supposed to be specific for phospholipids. By means of a Zeiss integration eyepiece following the method described by Hennig[3], the phospholipid content expressed as a surface percentage was determined in sections of the pineal gland. The integration eyepiece contains a grid showing a number of testing points. The number of times phospholipid droplets were hit by these testing points was counted, and from this number the surface percentage could be calculated. The way the method has been used in this problem must be looked on as being semi-quantitative. The results of the measurements in series I are plotted in Fig. 2; that of the measurements in series II, III and IV in Fig. 3. For each group of 6 animals the mean value of the phospholipid content pro-pineal gland was calculated and indicated in the graph by a dot. Besides this the highest and the lowest value in a group were also plotted.

As is shown in Fig. 2, just before ovulation the phospholipid content of the pineal gland is lowest. It increases after ovulation, reaching its maximum at di-œstrous. In Fig. 3 the animals of series IV demonstrate that the phospholipid content of the pineal gland decreases wit increasing age, at least during the period of life investigated. Ovariectomy at 4 and 8 weeks gives a steep ris of the phospholipid content though this rise is mor pronounced after ovariectomy at 8 weeks (series III than it is after 4 weeks (series II). Apart from an increase i pineal phospholipids due to ovariectomy, series II an III show that the phospholipid content decreases durin the ageing of the animals. The curves of the ovariectomized animals run fairly parallel to that of th controls.

Although interpretation of the results is rathe premature, some remarks seem worth while. As can b seen from Fig. 1, the obvious fluctuation in the phospholipid content of the pineal gland is linked to the œstrou cycle, that is, to the state of activity of the ovaries. Thi is supported by the fact that ovariectomy invariabl causes an increase in pineal phospholipid content. It remains to be investigated whether this effect is due t either a primary gonadal or a primary hypophysea influence.

Each first group of series II and III was killed 3 day after ovariectomy. It is remarkable that the increas of pineal phospholipids is much less in series II (ovariectomy at 4 weeks) than it is in series III (ovariectom at 8 weeks). The mean values for controls and experimental animals at 4 weeks are 32·72 per cent and 36·2 per cent respectively; at 8 weeks 26·60 and 32·60 per cent the differences being 3·5 and 6 per cent and the ratio being 1·4/1·3 and 1·6/1·3 respectively. Apparently th influence of ovariectomy is less at 4 weeks. Probably this difference is due to the fact that the endocrin apparatus, responsible for reproduction is less activ at 4 weeks than it is at 8 weeks.

As stated before, the curves of the ovariectomize animals and the controls run fairly parallel in Fig. 3 Apart from the animals belonging to series III whic were killed at 10·5 weeks, the mean values of th phospholipid content of the pineal glands of both experim

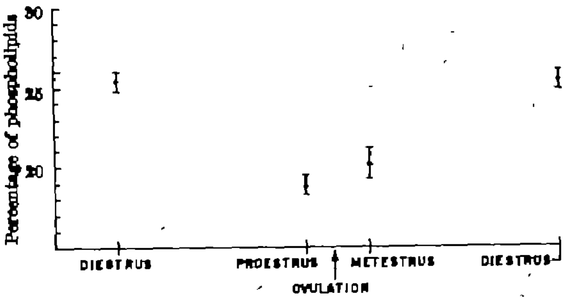

Fig. 2. The pineal lipid content in different phases of the œstrous cycle

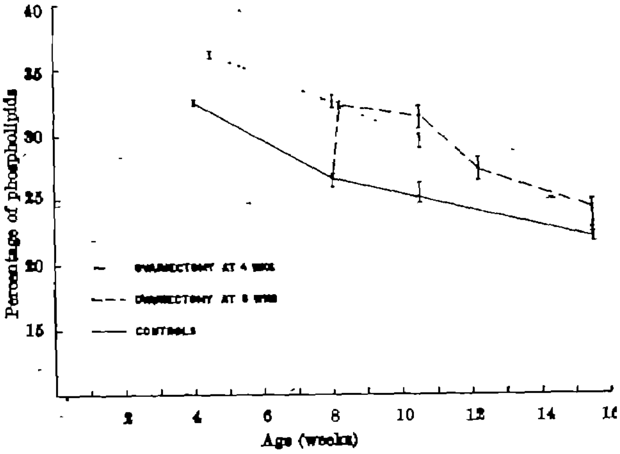

Fig. 3. The pineal phospholipid content after ovariectomy and in control animals

ental series can be connected by an almost straight line. Apparently ovariectomy causes a change in activity of the pineal, as concerns the accumulation of phospholipids, which is not merely due to operation trauma. The results obtained strongly suggest that it is due either to deprivation of ovarian hormones or to overproduction of gonadotrophic hormones, as is shown by the fact that the effect is not a temporary one. The exact interrelation between epiphysis, hypophysis and gonads, as well as the part the phospholipids played in this interrelation, remains still to be investigated.

Regulation by Calcium of Parathyroid Growth and Secretion *in vitro*

Evidence that the concentration of calcium in the blood directly controls parathyroid activity has been obtained in whole animals[1,2]. Gaillard[3] found that parathyroid glands could be maintained in organ cultures and that the medium in which these glands had been cultivated could stimulate bone resorption. These findings prompted me to examine the effect of changes in calcium concentration in the medium on parathyroid growth and secretion *in vitro*.

Parathyroid glands, dissected from 13-day chick embryos, were cultivated on a layer of agar held at the surface of a fluid medium by a metal screen cut to fit a small embryological watch glass. The culture fluid consisted of 30 per cent rat serum in a chemically defined nutrient medium[4]. Parathyroid glands were also dissected from adult male rats (140–200 g). These were placed on millipore filter and cultured as above except that 50 per cent rat serum in a modified Eagle's medium[5] was used. Concentrations of calcium, inorganic phosphorus, magnesium, and strontium were varied, sodium bicarbonate was 25 m.moles/l., and the explants were cultivated under 5 per cent carbon dioxide, 95 per cent oxygen. After 48 h the glands were fixed in Zenker's fluid and serial sections were cut. These were examined for mitotic rate, cell size, and the ratio of cytoplasmic to nuclear volume (*C/N* ratio) as determined by Chalkley's method[6].

Table 1. Effect of Calcium Concentration in the Medium on Relative Abundance of Cytoplasm (*C/N* Ratio) in Parathyroid Glands

	Medium calcium concentration (m.moles/l.)	No. of glands	*C/N* ratio (mean ± *S.E.*)	*P* value

* Plus 2·5 mM/l. magnesium chloride. † Plus 3·1 mM/l. strontium chloride.

Although the *C/N* ratio varied in different experiments, in any one experiment it provided an index of the relative stimulation or suppression of cytoplasmic growth by the media used (Table 1). After cultivation in a medium low in calcium concentration, explants of parathyroids from chick embryos and adult rats showed abundant cytoplasm (Fig. 1). A high medium calcium concentration caused a marked decrease in the amount of cytoplasm with but

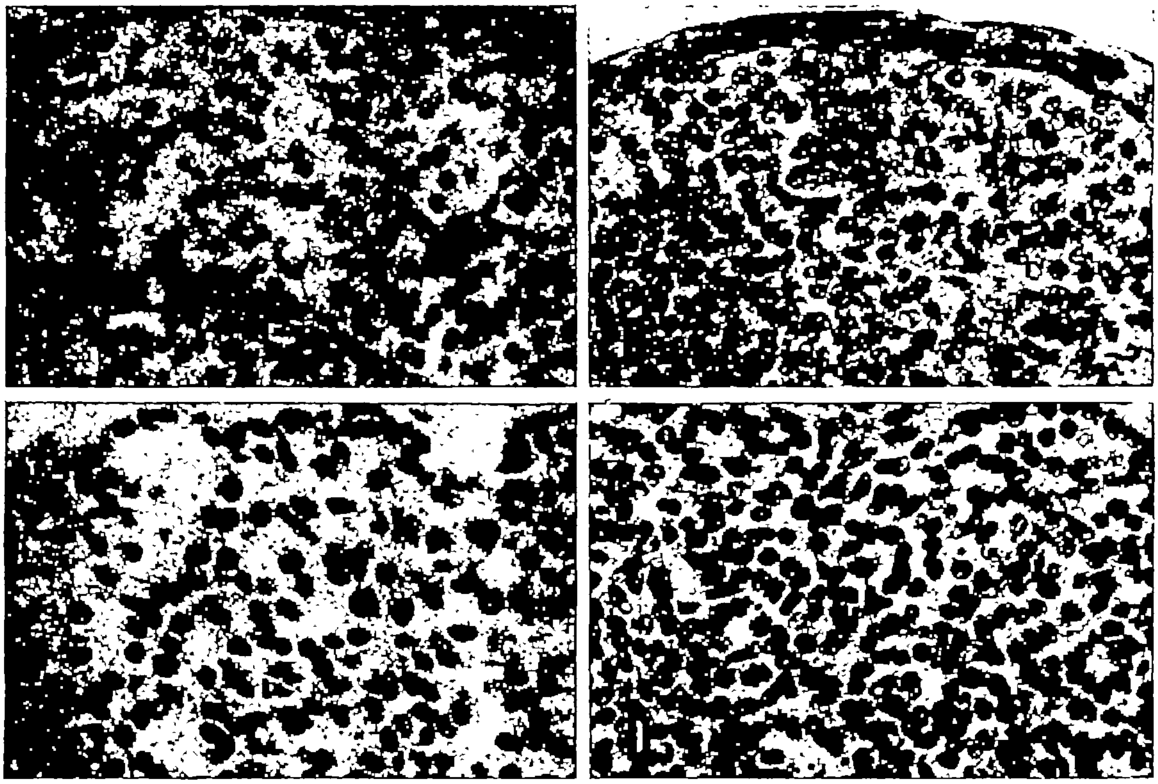

Fig. 1. Effect of low calcium (*A*) and high calcium (*B*) concentration in the medium on paired parathyroid gland cultures from a chick embryo (experiment 1). Note mitoses (arrows) in *A*. Effect of low calcium (*C*) and high calcium (*D*) concentration is also seen in parathyroids from an adult rat (experiment 5). (Hæmatoxylin and eosin stain, × 200)

little change in nuclear size. In embryonic chick glands a significant difference in mitotic rate was observed. In Exp. 1 there were 1·3 ± 0·1 mitoses/1,000 cells in glands cultivated in low calcium medium, compared with 0·6 ± 0·1 mitoses/1,000 cells in high calcium medium. In adult rat glands mitoses were rare. When calcium concentration was decreased to 0·2 m.mole/l. using dialysed serum (Table 1, Exp. 3) cell disruption and a decrease in cytoplasmic volume occurred. At higher calcium concentrations there was an inverse relationship between calcium and *C/N* ratio. The cytoplasm was less abundant in this experiment than in others, perhaps because some growth factor was lost from the serum during dialysis. Changes in calcium concentration did not affect *C/N* ratio in cultures of either embryonic or adult thyroid, kidney, and lung. Increasing inorganic phosphate concentration from 1 to 3 m.moles/l. when calcium concentration was low did not result in further stimulation of the glands. Replacement of the calcium by magnesium to maintain a constant divalent cation concentration did not prevent the low calcium effect (Table 1, Exp. 2). Addition of 3·1 m.moles/l. of strontium had less suppressive effect than a much smaller (0·9–1·6 m.mole/l.) increase in calcium concentration (Table 1, Exp. 4).

The secretion of cultivated parathyroid glands was measured by an *in vitro* assay technique recently developed in our laboratory[7]. The assay is based on the ability of parathyroid extracts to stimulate resorption of embryonic bone in organ cultures. The embryos were obtained from pregnant rats which had been injected with calcium-45 three days prior to death. Paired shafts of 18–19-day radius or ulna were cultivated. Resorption was measured by the release into the medium of the calcium-45 which had previously been incorporated in the embryo bones *in vivo*, and also by the change in stable calcium concentration in the medium at the end of 72-h cultivation. In these experiments adult rat parathyroids were grown in media of 0·9–3·1 m.moles/l. calcium concentrations. At the end of cultivation of the parathyroids, the media were mixed 1 : 1 with fresh control medium of varying calcium concentration to bring the concentration of the mixture to 2·1 m.moles/l. These reconstituted media were then tested against fresh control media which had never been in contact with parathyroid glands (Table 2). Media originally low in calcium (0·9–1·6 m.mole/l.) which had stimulated or incompletely suppressed parathyroid growth were found, when reconstituted, to contain bone-resorbing activity. Medium originally high in calcium which had suppressed parathyroid growth contained no more bone-resorbing activity than did control medium. The active media caused the release of 80–150 per cent more calcium-45 than did control medium. This effect lies between that obtained with 0·1 and 1·0 units/ml. of parathyroid extract[7].

Table 2. EFFECT OF RECONSTITUTED MEDIA FROM PARATHYROID GLANDS ON CALCIUM RELEASE FROM EMBRYONIC BONES

	No. of bones	Medium calcium concentration Initial	Reconstituted (m.moles/l.)	Final	^{45}Ca release (c.p.m./bone)

* Significantly different from control, $P < 0·05$.
† Significantly different from control, $P < 0·01$.

The experiments recorded here provide direct evidence that a low concentration of calcium stimulates and a high concentration suppresses the cytoplasmic growth and secretion of the parathyroid glands. This response appears to be relatively specific for parathyroid tissue and for the calcium ion. The system used is a convenient model for analysis of the mechanism by which calcium regulates the parathyroid glands.

This work was begun at the Strangeways Research Laboratory, Cambridge, England, while I was a Special Research Fellow of the U.S. Public Health Service. I thank Dr. Honor B. Fell, director of the Laboratory, for her encouragement and advice.

Release of Catecholamines from the Atrium of the Dog by Tyramine

IT was suggested in 1958 by Burn and Rand[1] that tyramine acts by releasing catecholamines from tissue 'stores'. Direct evidence to support this has been sought, but with inconclusive results.

In the work reported here, an effort was made to demonstrate the release of endogenous catecholamines from the isolated right atrium of the dog by tyramine. The atrial β receptors for catecholamines were previously blocked by dichloroisoproterenol (DCI). The isolated right atrium of the dog, bathed in balanced salt solution at 31° C, was incubated with tyramine for 15 min. At the end of the incubation period the presence of catecholamines in the bathing fluid was determined by transferring the bath fluid to another tissue-bath containing a spiral aortic strip from a reserpinized rabbit. Suitable controls were devised to exclude the possibility that the response of the aortic strip was due to spontaneous release of a vasoactive substance from the atrium, or to the direct action of tyramine on the arterial strip itself.

The release of small quantities of a vasoactive material by tyramine was repeatedly demonstrated in six such experiments on the atria of the dog (Fig. 1). The constancy of the magnitude of response relative to the

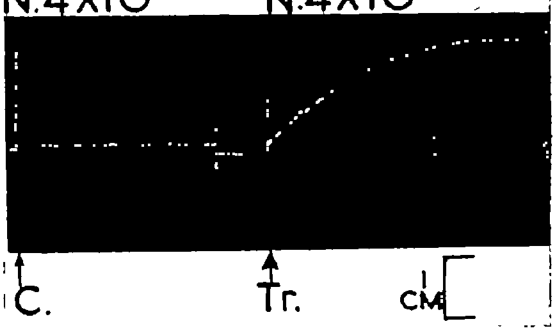

Fig. 1. Responses of reserpinized rabbit aortic strip to (*N*) noradrenaline, (*C*) control and (*Tr*) atrial bath fluid after incubation with tyramine

catecholamine sensitivity of the strip suggests that the vasoactive substance was itself a catecholamine[3].

Cyproheptadine[3] (an anti-histamine and an anti-5-HT agent) decreased greatly the response of the aortic strip to added 5-HT, and abolished the response to added histamine. There was no detectable change in the response to added noradrenaline or to the vasoactive material.

Observations on a rat fundal strip and on an isolated guinea pig ileum indicated that tyramine does not release 5-HT or histamine in amounts adequate to stimulate the spiral aortic strip. The observations on the guinea pig ileum also suggested that a vasoactive polypeptide, for example bradykinin, was not responsible.

It was concluded that the vasoactive material was almost certainly a catecholamine released from the tissue 'stores' of the atrium by tyramine.

Antiserum Inhibition of the Œstrous Cycle in Normal Rats

Evidence for the neutralization of pituitary gonadotrophic hormone activity in mammals by immunological procedures has been reviewed in several articles. The specificity of the hormone neutralizing (antihormone) effect of the antiserum has been suggested by many of the investigations reviewed, but there has been some question as to the specificity of this effect, because of the possible role of impurities or trace antigenic contaminants in the hormone preparations used[1–4]. A recent report[5] describes the successful inactivation of a purified pituitary follicle-stimulating hormone (FSH); the marked follicular stimulation obtained by the injection of sheep FSH into immature hypophysectomized female rats could be completely inhibited with rabbit antiserum to the homologous FSH. This inhibitory effect was found to be dependent on the dosage of antiserum used. Other recent studies have reported the neutralization of endogenously secreted pituitary interstitial-cell stimulating hormone (ICSH) in the normal immature[6–8] and mature[8] male rat and in the immature female rat[9], with the use of antiserum prepared against purified sheep ICSH.

This is a preliminary report showing that rabbit antiserum to purified sheep ICSH can inhibit the œstrous cycle in adult female rats. Supporting evidence is presented to indicate the specificity of the observed antihormone effect. A detailed report of the inhibition (with the same antiserum) of testicular development and maturation in the normal male rat is now awaiting publication[10].

Antiserum was prepared by a method previously described[8]. Young albino male rabbits were immunized by injecting them subcutaneously with purified sheep ICSH (N.I.H.-*LH*-*S*1, received through the courtesy of the Endocrine Study Section of the National Institutes of Health: this preparation has been fully characterized; the assay data have been presented elsewhere[10]) in Freund's adjuvant, over a period of 3–5 months (total dose of 4–6 mg per animal). The last injection (0·25 mg) was given in saline 8–10 days prior to bleeding. The antiserum was absorbed to remove non-specific antibodies against homologous (sheep) serum proteins.

Before antiserum treatment was started, the vaginal cycling patterns of adult female Long–Evans rats were followed for a period of 16 days. Animals were selected for the experiment on the basis of a normal 4–5 day cycling pattern, as determined by examination of their vaginal smears (stained with Giemsa). The antiserum injections were given in gradually increasing dosages (0·5 ml. to 3·0 ml. per day) over an 11-day period, with an average daily dose of approximately 1·5 ml. All antiserum-injected rats showed sustained dioestrus vaginal smears after the second or third day of treatment. Regardless of the particular phase of the vaginal cycle in which the animal happened to be at the time that the injections were commenced, the antiserum administration resulted in a complete cessation of cycling, stopping it in the same phase in all animals. The vaginal cycling of animals treated with normal rabbit serum (NRS) showed no significant differences from that of the non-treated control animals. It was of interest to note that the antiserum-injected animals commenced to cycle again approximately 10 days after treatment had been discontinued. Histological examination of the ovaries of antiserum-treated rats revealed that the interstitial cells were as deficient in appearance as those in hypophysectomized animals. The recovery of normal vaginal cycling was accompanied by a restoration of the appearance of these cells to normal.

Rats in one of the antiserum-treated groups were injected 24 h before death with 1 µc. of iodine-131 to determine the effect of antiserum treatment on thyroid function. It was found that the uptake of iodine-131 by the thyroid glands from the antiserum-injected rats was not significantly different from that for animals injected with NRS. This finding suggested that the ICSH antiserum did not contain antibodies against thyroid-stimulating hormone, as demonstrable by this method.

There was no evidence to indicate toxicity of the antiserum, as judged by the lack of effect on gain in body-weight and adrenal or thymic weights. If anything, the antiserum administration resulted in a slight but definite increase in body-weight gain. The foregoing findings suggested that the antiserum did not contain any detectable antibodies against rat pituitary growth hormone or adrenocorticotrophic hormone. Still another test which indicated the specificity of the antihormone effect was the observation of precipitin reactions in agar diffusion plates[11]. Using a technique previously described[12], it was found that the minimum detectable amount of the homologous hormone (sheep ICSH, N.I.H.-*LH*-*S*1) was of the order of 2 µg, yet the same antiserum did not give a positive precipitin reaction with varying doses (2–200 µg) of any of the other known anterior pituitary hormones in highly purified form. All hormones had been obtained from the homologous (sheep) species except for thyroid-stimulating hormone which was bovine in origin. The results of the various tests mentioned here strongly suggested that the antihormone effect of the antiserum may be dependent on a specific antigen–antibody interaction. A detailed report of these studies in female rats will be presented elsewhere.

HÆMATOLOGY

Coagulation of Blood in Temperature Acclimatization

PROLONGED clotting and prothrombin times as a function of lower blood temperature have been observed in various species *in vivo*[1–4] and *in vitro*[5]. The *in vivo* observations were made in æstivating and hibernating mammals[2–4] and with human blood from blood vessels where a differential in temperature had been demonstrated[1]. By contrast, Tadzer[6], using the rat in a study of hypothermia of short duration and uncomplicated by shock, did not find prolonged thrombin times; Lasch *et al.*[7], working with dogs, even obtained shorter clotting times on cooling, and a prolongation, due to an increase in heparin, on rewarming.

Comparatively little has been reported on the effect of prolonged adaptation to a hot or cold environment on blood coagulation, particularly when body temperatures remain near normal. Mills *et al.*[8] reported an increase in hæmorrhagic deaths in vitamin K-deficient rats exposed to the equivalent of tropical heat, as compared with animals kept in temperate coolness. Sutherland and Campbell[9] reported shorter prothrombin, but markedly increased clotting times in cold-adapted rabbits. The investigation reported here discusses the prothrombin and clotting time of adult Leghorn chickens maintained at three different ambient temperatures.

A total of 55 female and 24 male birds, approximately 1 year old, were available. They were kept in individual cages in temperature-controlled rooms at, respectively, 32° C and 60 per cent relative humidity ('hot'), 21° C ('control'), and 0° C ('cold'). In the second and third rooms the humidity was not controlled. At the time of testing all birds had been in their respective environments in excess of three months. Blood samples were taken by venipuncture from a brachial vein with siliconized syringes and whole blood clotting and prothrombin times measured, the latter by a one-stage method, using acetone dehydrated chick brain powder as a source of thromboplastin. Details of the methods have been described elsewhere[10], except that citrate rather than oxalate was used as an *in vitro* anticoagulant.

Table 1. PLASMA PROTHROMBIN AND WHOLE BLOOD CLOTTING TIMES OF ADULT BIRDS KEPT AT THREE ENVIRONMENTAL TEMPERATURES*

Environmental temperature (° C)	Prothrombin time			Blood coagulation time		
	$\text{sec}^{-1} \times 10^4$	sec		$\text{min}^{-1/2} \times 10^4$	min	
Females						
0	612 ± 10†	16·3	(19)‡	29·6 ± 2·6	11·4	(20)
21	600 ± 9	16·7	(17)	29·8 ± 3·1	11·2	(19)
32	568 ± 11	17·6	(19)	28·6 ± 2·0	12·2	(20)
Males						
0	632 ± 9	15·8	(5)	36·6 ± 3·3	7·5	(5)
21	611 ± 10	16·4	(10)	27·6 ± 1·7	13·1	(10)
32	586 ± 19	17·1	(9)	25·0 ± 1·7	16·0	(9)

* Since prothrombin and blood clotting times do not follow a normal distribution, appropriate transformations of individual values were used for all calculations, and mean values (columns 2 and 4) reconverted to conventional values (columns 3 and 5).

† Arithmetic mean ± *S.E.*

‡ No. of birds sampled.

Table 1 shows a general trend towards hypocoagulability with increasing environmental temperature. Plasma prothrombin times of females kept at 32° C were significantly longer ($P < 0·01$) than at the control and cold environment. Equivalent changes in the males fell short of statistical significance, probably due to the smaller number of males available. The whole blood clotting time of the males kept in the hot environment, however, was significantly longer ($P < 0·01$) than that of the control birds. Although changes in clotting time in the hens maintained at 32° C showed the same trend, they were not statistically significant.

Prolonged exposure to high and low ambient temperatures was accompanied by certain physical and physiological changes. Thus, compared with the controls, both the 'hot' and 'cold' birds lost body-weight: 13 and 11 per cent, respectively, for the females, and 7 per cent in both environments for the males; the females also decreased in productive activity (21 and 28 per cent reduction in egg production), but diverged in feed consumption, which was 67 and 63 per cent of normal for females and males in the hot environment, and 106 and 152 per cent of normal, respectively, for the birds in the cold. The smaller increase in the females is probably associated with decreased egg production due to cold-stress. Hæmatocrits (microtubes), measured in the females only, increased with decreasing ambient temperature (23·2, 25·4 and 29·0 in the (hot), (controlled) and (cold) environment, respectively), but deep body temperature, determined with a flexible thermistor inserted 10 cm through the cloaca, was not significantly different among the three groups. Thus, differences in blood temperature, as observed in the dormant state or in hypothermia, could not explain our observations.

Mills[1] considered the possibility of a disturbance in the production of vitamin K by intestinal bacteria under conditions of tropical heat; as evidence he cites data indicating a much higher prevalence of hæmorrhagic disease of the new-born in southern than in northern U.S. cities. At the present state of knowledge it must be considered doubtful, however, that intestinal synthesis plays a significant part in the provision of vitamin K for the chicken. In our work, there is a possibility that, in connexion with the lower hæmatocrit of the 'hot' birds, hæmodilution might promote decreased levels of prothrombin and possibly other clotting factors. Lastly, consideration should be given to a possible relationship between the coagulation picture and the changes in the rate of overall metabolism, as indicated by the differences in feed consumption and in body-weight data among the various groups.

Hæmoglobin in a Flatworm

ALTHOUGH the presence of hæmoglobin in free-living flatworms (Turbellaria) has been recorded by several authors[1–4], the pigment has not yet been investigated in detail. A large sample of the rhabdocœl, *Phaenocora unipunctata* (Orsted 1843), was obtained from mud from Coe Fen, Cambridge. These worms were found to contain hæmoglobin, and a preliminary examination was made of the properties of this pigment and its distribution within the tissues of the animal.

The worms, the largest of which were about 5 mm in length, were kept in the laboratory in shallow dishes containing about 0·5 in. of mud under 1 in. of water. They crawled and burrowed actively, usually feeding on the oligochæte worm *Tubifex*, present in the mud. The reddish colour of the worms was due not only to their own hæmoglobin but also to the presence of food hæmoprotein in their gut and their red-brown tanned eggs. Worms were collected from the dishes as required with a Pasteur pipette and transferred into clean water. The worms were left in clean water for several days before proceeding to other studies to avoid interference from food hæmoprotein.

Glass beakers, each containing ten worms, were set up either without food, or with food free from hæmoprotein ('Farex' baby food). Those beakers for experiment were filled with de-gassed tap-water and immediately covered with liquid paraffin. The control beakers were filled with tap-water equilibrated with air. No obvious change in colour or activity of the worms was noted after a week, except that worms without food became much shrunken at the posterior end, having apparently metabolized a considerable portion of their reserve substances. The disappearance of some worms and the appearance of winter eggs in all beakers indicated that all the worms had been under some stress. Visual examination, however, failed to reveal any obvious difference in hæmoglobin content among the various batches of worms, although those in de-gassed water had concentrated in or near the liquid paraffin layer. The results suggest that this worm does not increase its hæmoglobin content under conditions of oxygen deficiency, as concluded by Fox[4] with an unidentified species of *Phaenocora*.

The presumed function of the hæmoglobin as an oxygen carrier was tested by confining a number of worms in a small volume of water at the bottom of a Thunberg tube. A close-fitting rubber plug was used to keep them at a suitable density for spectroscopic examination, that is, 25–30 worms in 1 ml., and a preliminary examination showed the characteristic bands of oxyhæmoglobin at about 580 and 540 mμ. After 2 min, the normal activity of the worms was reduced and the oxyhæmoglobin spectrum had been replaced by an absorption band of cytochrome at about 560 mμ. This suggests that a *B* type of cytochrome is the major component of this system present in the worm. The β-band of this cytochrome component could not be seen, showing that the cytochrome is in much lower concentration than the hæmoglobin. When sufficient air was allowed to enter the Thunberg tube, the cytochrome band was replaced by those of oxyhæmoglobin. This cycle was repeated several times. The worms recovered their normal activity and the oxyhæmoglobin spectrum returned permanently when air was finally readmitted.

The distribution of the pigment was examined by a sodium nitroprusside–benzidene technique which gives a reaction with hæmatin compounds[5]. This was compared with the distribution of ferric iron found with Perl's technique[6]. For the latter technique, worms were fixed for two days in 5 per cent formalin in 0·9 per cent sodium chloride, embedded in paraffin wax and sectioned at 7μ. Complete worms were used for the hæmatin investigation after fixing for 24 h in 70 per cent ethanol. Hæmatin was found to be most concentrated on each side of the pharynx. It was also present between the eyes and extended dorsally over the whole length of the gut, but it was absent above the pharynx. The concentration appeared to be greatest at the anterior end, in agreement with visual observation, but it was also present in the posterior portion of the body. Ferric iron was found to be distributed evenly in the tissues of the anterior part of the worm and it was equally concentrated just beneath the dorsal epidermis throughout the whole length of the worm, except in the region over the pharynx. Comparison with the hæmatin distribution suggested that some ferric iron was separate from the hæmatin compounds. Prenant[7] examined several species of turbellarian and found that they did not contain an appreciable amount of hæmatin, although the parenchymal tissues were rich in iron.

The small amounts of hæmoglobin present and the lack of a suitable means of culturing large numbers of the animals made it difficult to determine the physico-chemical properties of this pigment. We calculated that in spite of their distinct redness each worm provided only 1 or 2 μg of extractable hæmoglobin. We therefore offer the following observations merely as a guide for further work.

The pigment was extracted as a yellow solution by homogenizing up to two hundred worms at a time in a 'Teflon' homogenizer. The solution, clarified by centrifugation, showed the characteristic bands of oxyhæmoglobin. These became undetectable when the air pressure was reduced to 2 mm of mercury. A sample of extract was analysed for us by Mr. B. Boon, of the Biochemistry Department, in a Spinco model *E* ultracentrifuge. Although the experiment was not completely satisfactory because of the low concentration, it nevertheless suggested that the coloured material moved in association with the main peak. This seemed to comprise all the sedimenting material and had an uncorrected S_{20} of 2·3 ± 0·4. A similar sample was electrophoresed on polyacrylamide gel at *p*H 8·6 and was found to move two and a half times as fast as a control sample of horse hæmoglobin.

We thank Mr. S. Prudhoe of the British Museum (Natural History) for identifying the flatworm. He also informed us that the whole body of another aquatic flatworm, *Rhynchomesostoma rostratum*, has a pinkish coloration[8]. Moseley[1] mentioned that *Dendrocoelum lacteum* has a red colour. The only previous reference to hæmoglobin in *Phaenocora* was given by Fox[4], but Gilbert[9] describes red pigmentation in three species of this genus, *P. highlandense*, *P. virginiana* and *P. kepneri*. In describing *P. highlandense*, Gilbert states that the anterior end is coloured a rich red as far back as the posterior edge of the pharynx where the colour is graded off into the colour of the body proper. He also records that he has occasionally found the same region in the other two species coloured a delicate rose, but never a deep red as in *P. highlandense*.

Our observations on the properties of the pigment suggest that it has a relatively high oxygen affinity, a low isoelectric point and a low molecular weight. The latter might be anticipated, since all known tissue hæmoglobins are of low molecular weight, usually about 18,000. It confirms, however, that we were not dealing simply with contaminating *Tubifex* hæmoglobin, the molecular weight of which is 3×10^6.

It appears that *Phaenocora* is not one of those invertebrate types in which the hæmoglobin concentration varies according to the oxygen tension of the environment[4]. It seems more likely that it is connected with the normal physiology of the animal. In this worm the pigment is concentrated around the muscular pharynx, and respiratory pigments often occur in or near muscular tissues in which sustained or powerful contractions take place.

HISTOCHEMISTRY

Electron Microscopy of Post-mortem Changes in Porcine Muscle

MARKED changes were noted in porcine muscle during the initial 24-h post-mortem period. These changes were of particular interest in relation to muscle structure and water-binding, as described by Briskey and Wismer-Pedersen[1].

Muscle samples from the longissimus dorsi were removed and fixed in osmic acid immediately as the animal was stunned, at the onset of rigor mortis[3] and 24 h *post mortem*. Afterwards, the samples were passed through a graded series of alcohol, embedded in methacrylate (1-part methyl to 4 parts butylmethacrylate) sectioned with the Porter-Blum ultramicrotome and examined in a Siemens electron microscope. Pictures were taken at an original magnification of 8,000. The longissimus dorsi muscle samples were removed from an animal that was subjected to 120° F temperature for 40 min *ante mortem*. The immediate post-mortem temperature of the longissimus dorsi was 110° F. The onset of rigor mortis began 15 min *post mortem* when the *p*H of the muscle was 5·6. Following the 24-h chilling period, the muscle exuded large quantities of moisture, exhibited a pale colour and appeared to be quite open in structure.

Fig. 1 shows the soft-watery muscle at the time of death. The muscle appeared to be in a contracted state with only a small portion of the I band visible. Only 15 min later a drastic change had occurred in the muscle as seen in Fig. 2. Even though some sectioning marks are present on the myofibrils, the I bands are clearly visible and the *M* line can be seen in some cases. Most dramatic are the ruptured mitochondria, the remains of which are scattered between the myofibrils. The appearance of the muscle 24 h *post mortem* is seen in Fig. 3. A complete banding pattern is shown; however, this does not mean the muscle structure is complete but may indicate an extraction of material from the muscle, thereby rendering the bands clearly visible. The appearance of the *A* band is quite important; the definite granular appearance may indicate that a disruption of the myosin filaments has occurred in this muscle, which had a rapid onset of rigor at a low *p*H, turned a pale colour, and exuded large quantities of liquid. There seems to be no evidence of precipitated proteins on the myofibrils, as suggested by Bendall and Wismer-Pedersen[3], for this type of muscle. However, it is possible that sarcoplasmic proteins could have collected on the myofibrils and washed off during fixation and dehydration.

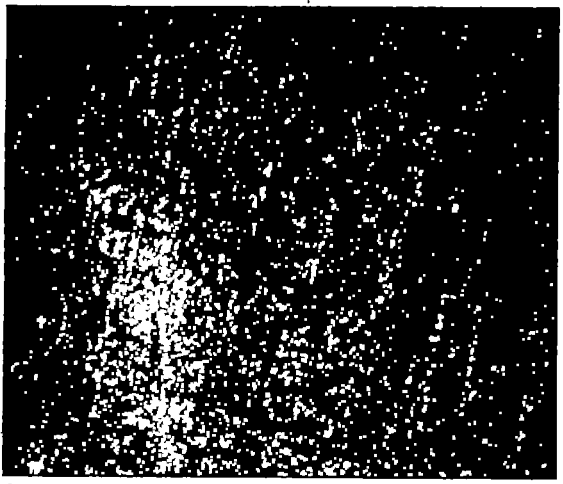

Fig. 1

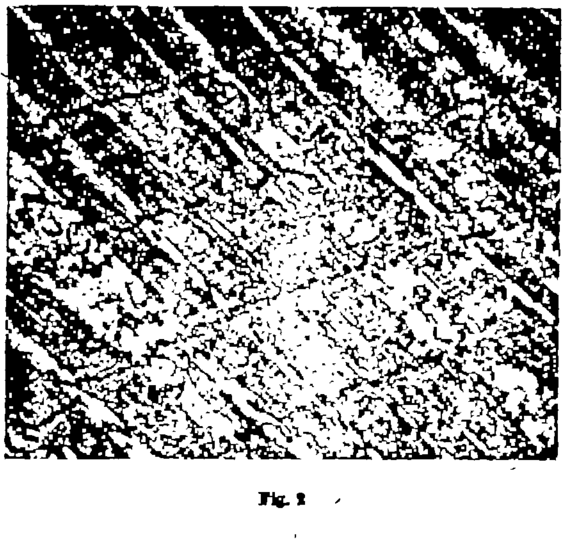

Fig. 2

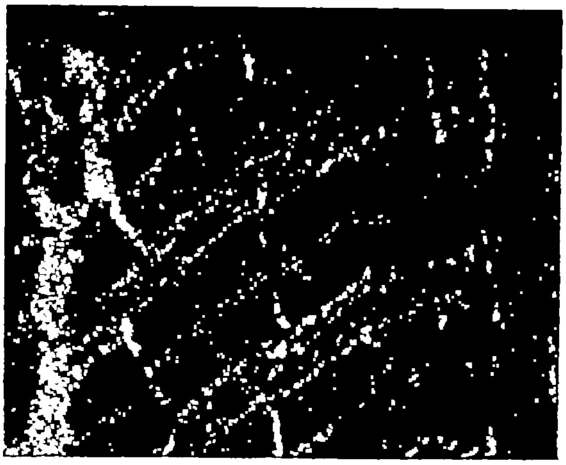

Fig. 3

The problem remains to relate the post-mortem changes in the ultrastructure of the muscle to its gross appearance and biochemical properties.

This investigation was supported by a research grant (*EF*-81-*C*3) from the Department of Health, Education and Welfare, U.S. Public Health Service.

A Colorimetric Method for the Quantitative Measurement of Total Lipids in Tissues

It is well known that the sudan and related dyes used for demonstrating lipids in histochemical technique dissolve in the lipid and can be re-extracted with fat solvents. Such oil-colorants are more soluble in oil than in the solvent used, and if an oil is shaken with a great excess of colorant solution, the oil will become saturated with colorant. Gomori[1] has introduced triethyl phosphate as a solvent for oil colorants in histochemistry for it has the advantage of being miscible with water. If the colorant is dissolved in triethyl phosphate, therefore, excess colorant may be removed by addition of water without re-extraction of colorant from the oil. The amount of oil will be proportional to the amount of colorant dissolved, and this may be measured photometrically.

It has been found possible to perform the whole procedure within a separatory funnel. The lipid extract is transferred in diethyl ether to a perfectly clean, dry funnel. A funnel of globular shape with little or no neck and short stem has been found best, for the funnel may be laid on its side so that the lipid solution is not brought into contact with the tap. By placing such a funnel on its side in a beaker of hot water the ether may be boiled off and the vapour removed with a current of air, or removed by reduction of pressure. A large excess of oil colorant dissolved in 60 per cent triethyl phosphate is then added and the flask gently shaken. The colorant should form a very concentrated but not necessarily saturated solution, and contain five drops of 'Teepol' or similar wetting agent per 100 ml. The funnel is allowed to stand and the excess hypophase run off. If the quantity of lipid is such that the colour of the phosphate solution is visibly reduced, a fresh portion is then added and the funnel shaken as before to ensure saturation of the oil with colorant. Water is then added, the funnel gently rotated, allowed to stand and the hypophase removed. This procedure is repeated. The coloured lipid which remains may be dissolved in acetone, and the solution made up to a known volume when the optical density may be measured photometrically or spectrophotometrically at the absorption maximum of the colorant used.

Oil red O has an absorption maximum around 512 mμ in most solvents and has been found to be best, for it is more soluble in aqueous triethyl phosphate than most oil-colorants, and is less easily precipitated on addition of water. The precipitate which forms is prevented from adhering to the lipid droplets and to the sides of the funnel by the wetting agent: too much of this must not be added nor the funnel shaken too vigorously or the lipid may be emulsified. Too little will cause adherence of the precipitate and introduce considerable error. The triethyl phosphate solution must also be free from precipitate, and should be filtered if necessary before use, for any precipitate it contains will remain in the oil after washing. The use of acetone in the final step has the advantage of making drying unnecessary since the acetone will take up any water left in the funnel. The absorption maxima of carotenoids which may be present in the oil are also well removed from that of oil red O. If carotenoids are present in quantity their effect may be reduced by exposure to light, oil red O being relatively stable. The anthraquinone oil-colorants such as sudan blue while preferable in having absorption maxima near or above 600 mμ are much less soluble in aqueous triethyl phosphate and tend to form troublesome precipitates. The procedure may be hastened by using a funnel that can be placed in a centrifuge.

The estimate of the quantity of oil present is dependent on the laws governing solution, so that different kinds of oil cannot strictly be compared. In practice for a given tissue and within a narrow range of temperature the method gives consistent results within an accuracy of 2 per cent down to at least 2 mg oil.

IMMUNOLOGY

Ribonucleic Acid Metabolism in the Plasma Cell Sequence

Examination of the immune response of rats to *Salmonella* antigens has confirmed a large body of evidence that plasma cells (mature and immature) are the chief producers of antibody[1]. Both in the primary and secondary responses, these specialized effector cells arise by multiplication and differentiation of primitive lymphoid blast cells, and do not seem to divide[2,3]. As each cell usually forms only one antibody[4], its ribosomes presumably are geared primarily to the production of a single protein. The ultimate source of the information for this synthesis is unknown, but presumably during production it must be encoded in ribonucleic acid (RNA). The present experiments were designed to approach this problem by examination of RNA metabolism in the different members of the plasma cell family *in vitro*. Tritiated uridine, a precursor of both deoxyribonucleic acid (DNA) and RNA, was used, the differential uptake into each being evaluated by digestion of the cells with the appropriate nucleases.

Popliteal lymph node cells from rats immunized with *Salmonella adelaide* flagella were suspended in a modified Eisen's[5] medium supplemented with amino-acids, vitamins and 5 per cent fœtal calf serum. After a short period of equilibration at 37° C., tritiated uridine was added to a concentration of 5 or 20 μc./ml. Two approaches were used:

(*A*) *Continuous presence of isotope*. Cells were kept in medium containing tritiated uridine for the whole of the experiment.

(*B*) *Short pulse of isotope*. Cells were incubated for 5 min in the presence of tritiated uridine, rapidly chilled in medium containing an excess of carrier uridine, washed and resuspended for further incubation in uridine-free medium. In either case, cell samples were taken at intervals, chilled, spun at 1,000*g*, resuspended in fœtal calf serum, smeared on gelatin-coated slides and fixed in 89 per cent methanol and 1 per cent acetic acid. Some smears were digested with ribonuclease, others with deoxyribonuclease and others with both enzymes *seriatim*. Then all smears, including undigested ones, were processed for autoradiography by Pelc's technique[6] using 'Kodak *AR* 10' stripping film. After 14-days' exposure, the mean counts of grains overlying the nucleus and cytoplasm of cells in the different categories were determined.

The most striking finding was that while plasmablasts incorporated tritiated uridine rapidly, mature plasma cells (the chief antibody-formers in micro-drop studies) exhibited little RNA turnover. Fig. 1 shows the result of a typical experiment using cells 4 days after secondary stimulation, with continuous presence of isotope. At all stages blast cells were labelled far more heavily than any other cell category, both in the nucleus, and, at later time points, in the cytoplasm. Mature plasma cells sometimes showed less incorporation into RNA than small lymphocytes. Pulse labelling experiments showed that most of, if not all, the RNA synthesis in blast cells occurred in the nucleus and that some RNA later moved to the cytoplasm. Counts continued to rise for about 1 h after

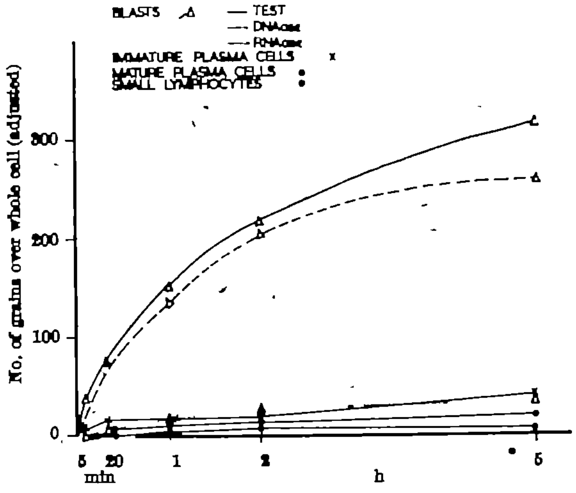

Fig. 1. Incorporation of tritiated uridine into lymph node cells of a 4-day secondary response. In this experiment 5 μc./ml. of tritiated uridine was continuously available to the cell culture. —— represents counts over cells from smears not digested by enzymes; – – – represents DNase digested blasts, and · · · · represents RNase digested blasts

PHYSICS DEPARTMENTAL LIBRARY

removal of the isotope, indicating progressive incorporation into macromolecular RNA[7]. Then total counts fell rather rapidly for the next hour and more slowly thereafter, suggesting a fraction with a rapid turnover rate, as well as a more stable fraction.

To determine whether the low RNA-metabolism in plasma cells was due to unphysiological conditions, *in vivo* experiments using foot-pad inoculation of tritiated uridine were performed. These completely confirmed the *in vitro* results. As had previously been noted by Schooley[8], mature plasma cells showed virtually no label. Schooley claimed that mature plasma cells merely released, and did not actually synthesize, antibody. To study this point, tritiated leucine incorporation was measured in our *in vitro* system. These experiments are subject to the reservation that no enzymatic digestions are available to determine whether the leucine actually entered protein, but it seems likely that free amino-acids would be removed from the cells by fixation and the extensive subsequent washing procedures. The results of a typical experiment are shown in Fig. 2. When tritiated leucine is continuously available to cells from 4-day secondary nodes, the initial rate of incorporation into mature plasma cells is two-thirds that into blast cells. Moreover, the kinetics suggest that the blasts are synthesizing predominantly stable protein, as the grain counts continue to rise; whereas the mature plasma cells appear to be turning over protein rapidly, since counts later than one hour show no further rise. This strongly suggests active antibody synthesis and export by mature plasma cells. The results are in close agreement with the overall picture presented by Helmreich *et al.*[9].

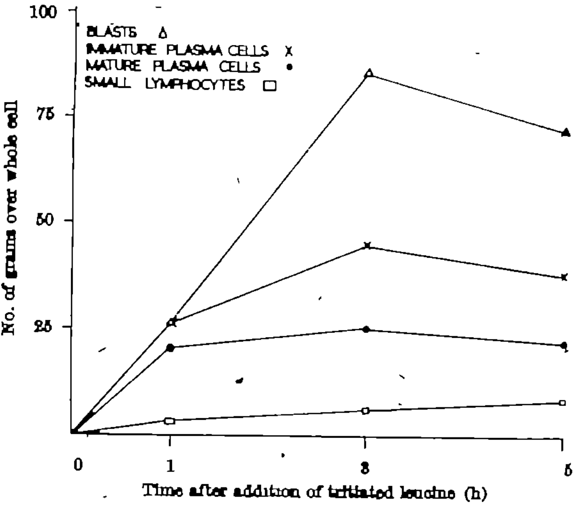

Fig. 2. Incorporation of tritiated leucine into lymph node cells of a 4-day secondary response. The medium contained 10 μc /ml of tritiated leucine

Accepting the results of the leucine experiments at face value, for every molecule of leucine taken into protein blast cells turn over thirty times as much RNA as do mature plasma cells.

In considering the source of nucleic acid templates for synthesis of antibody protein by plasma cells, we postulate that the ancestral blast cells manufacture the information during their active proliferative phase, and that this is passed down the maturation scale to the mature plasma cells. We feel that these preliminary results agree with the conclusion of Arnstein *et al.*[10] that where a specific protein is being produced, and all the efforts of the cell are directed towards the one function, any RNA analogous to the bacterial 'messenger'-RNA[11] is a stable entity attached to the ribosomes early in the cell's functional maturation.

We thank Sir Macfarlane Burnet for his interest in this work. It was supported by grant No. *AI*–03958 from the National Institutes of Health, U.S. Public Health Service, and by a grant from the National Health and Medical Research Council, Canberra.

BIOLOGY

A Specimen of *Morganucodon* from Yunnan

IN early July of 1948, while I was Rector of the Catholic University of Peking, I asked the Rev. Edgar T. Oehler, SVD, associate professor of chemistry in the University, to undertake an expedition to Yunnan in quest of *Bienotherium* fossil material, since I wanted to section and examine the otic region of the animal. The expedition was financed by Father Ralph Thyken, SVD.

On August 10, Father Oehler arrived at Lu Feng, and, with local help, set about his prospecting. In late September he found a skull about 1 in. in length, which is fairly complete as to lower jaw, upper jaw and cranium. It was found at Yang Tsao Ti (Goat Grass Place), a poor grazing area 25–30 min walk north-east of Lu Feng, in beds which were Bien's lower beds of the lower Lu Feng series. They are of a somewhat compacted red clay with purplish and light blue-green streaks and contain many calcareous nodules. The beds also contain *Bienotherium*.

A week after finding this fossil, Father Oehler sent it to me in Peking. It was eventually brought out of China, after my arrest by the Chinese Communists, by Dr. Wilhelm Brull, of the Catholic University, who gave it to me in February 1956.

I did not find time to describe this fossil as I had wished because at first I was recovering from more than four years of imprisonment in Peking; and then in July 1957 I went to Liverpool in England, where I was beset with many administrative duties. Around the beginning of 1960, I deposited this skull with Dr. K. A. Kermack, of University College, London, whose assistant, Mrs. Frances Mussett, undertook the delicate work of cleaning it.

Dr. Kermack has sent me stereoscopic photographs of diagnostic portions of this fossil. It is quite evident that this fossil comes close enough to the type of *Morganucodon* to place it in the same genus. I plan eventually to describe this fossil fully and in detail. Due to circumstances there may be a long delay before I can do this, and in view of the importance of the specimen a preliminary description seems justified. It is the first complete skull of any Mesozoic mammal of pre-Upper Cretaceous age. It has also been possible to observe in it the reptilian jaw joint between the quadrate and articular postulated in *Morganucodon* by Kuhne[1] and Kermack and Mussett[2] but not previously seen.

Morganucodon oehleri sp. nov. *Derivation of name.* In honour of Rev. Edgar Theodore Oehler, the discoverer of the specimen.

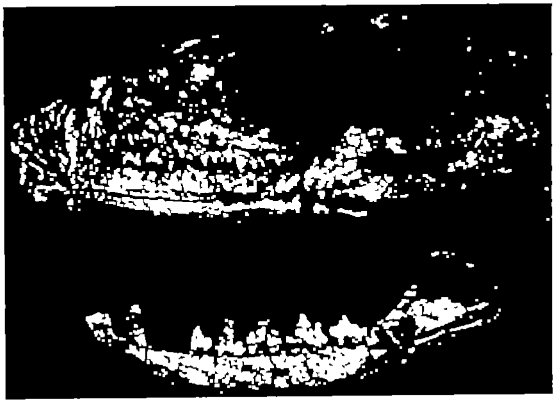

Fig. 1. *Morganucodon oehleri* sp. nov. Lateral view of skull and lower jaw and medial view of detached right ramus of lower jaw. (× *c*. 3)

Material. Holotype at present in the Zoology Department, University College, London. The partial brain-case mentioned by Patterson and Olsen[3] as *C.U.P.5* is almost certainly referable to the same species.

Horizon and locality. Lower beds of Lower Lu Feng Series at Yang Tsao Ti, Lu Feng, Yunnan, China.

Diagnosis. Lower molariform teeth larger than in *Morganucodon watsoni* (three fully erupted teeth together measure 5·5 mm in length). Dental formula differs from any of the specimens from Wales referred to *Morganucodon* by Kermack and Mussett[4] by having four premolariform and three molariform teeth in the upper jaw. In the lower jaw the formula is the same as in some of the Welsh forms, three premolariform and four molariform.

The presence of *Morganucodon* in the Lower Lu Feng Beds would suggest that they are of the same age as the Welsh fissures containing this genus—Rhaetic or Basal Liassic (Harris[5]).

Introductions of Exotic Fish

AT the tenth session of the Indo-Pacific Fisheries Council held in Seoul, Korea, recently, it was recommended that a register of introductions of exotic fish should be compiled by the Food and Agriculture Organization and that institutions and scientific workers should be asked to assist in this. I have undertaken to compile a list of all the introductions of *Tilapia* spp. into countries where they are not indigenous. *Tilapia* has already been introduced extensively in a number of countries, and if records are not compiled soon it will not be possible to ascertain the identity of any particular fish. This has already proved the case in some parts of Africa, where fish identified as a particular species in one area have proved different from fish given the same specific name in another area.

The *Tilapia* spp. are proving valuable fish in pond culture, and they can be considerably improved by judicious genetic selection and hybridization. For such a programme to be successful it is essential that stocks should be standardized and of known origin, and a start has been made in this Institute to standardize our own stocks. Since in many countries distribution of fish fry for pond culture is carried out by Fisheries Departments, there is no reason why these fish should not be improved standardized strains. In addition *Tilapia* spp. have become increasingly important as laboratory animals for behavioural and physiological research and it is essential that identity of the strains used should be known, as is the practice with other laboratory animals.

I would therefore request all those who have introduced *Tilapia* spp. into countries where they are not indigenous to co-operate in this compilation by sending me details of the origin, date of introduction and place of introduction of any species of *Tilapia*. In addition I would urge all those working with *Tilapia* spp. to bring about the standardization of their stocks by careful selection. Copies of the compilation on *Tilapia* will be deposited with the Food and Agriculture Organization for further compilation into a larger register.

Spiralization in Tails of Mammalian Spermatozoa in Hypotonic Media

IT was noted by Kölliker[1] that treatment of mammalian spermatozoa with water brings about coiling and spiralization of their tails. The present investigation, chiefly made on ejaculated bull spermatozoa, but supplemented by observations on sperms from man and rabbit, confirms these observations. Hypotonic solutions (calcium-free Ringer solution plus distilled water) induce in spermatozoa a very intense swimming without rotation around the longitudinal axes, and—with increasing hypotonicity—a progressive curving and bending of their tails which later coil into spirals (Fig. 1).

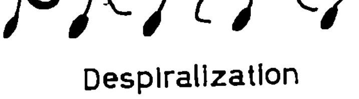

Fig. 1

Despiralization (Fig. 1) sets in after spiralization, and proceeds gradually at a higher rate at higher degree of hypotonicity. Maximum frequency of spiralized spermatozoa (up to 80 per cent), when counted after 20 min, is obtained in the hypotonic medium, 1 + 4 (one part isotonic Ringer + four parts distilled water). After 30–45 min in (1 + 4) rather good swimming still results, when the cells are brought back to isotony.

The process leading to spiralization seems not to depend on pure swelling. This appears from experiments in which 3·5–10 per cent of polyvinylpyrrolidone or 6–18 per cent of the polysaccharide dextran were added to the (1 + 4) medium, making it isotonic or hypertonic without affecting the phenomenon studied. On the other hand, repeated washing, cold shock, ageing, and storing are inhibitory to the spiralization, as is pretreatment of the cells with 10^{-3} M mersalyl or *p*-chloromercuribenzoate, substances which also cause despiralization of spermatozoa in hypotonic media. Cysteine abolishes the action of these —SH reagents. In a series of ejaculates taken immediately after each other, the frequency of spirals in the (1 + 4) medium first rises, then decreases. Thus the state of physiological maturation[2] seems to be of importance. Semen samples of high viability, that is, long survival in isotonic Ringer's solution at room temperature, give higher frequencies of spiralized cells than such of low viability. Low temperature very markedly reduces the durability of the spirals. Furthermore, curving and bending of the sperm tails as described here are immediately evoked also by hypertonic solutions of glycerol (15–20 per cent in isotonic Ringer), yet without spiralization. No tested hypertonic concentrations of sodium chloride, saccharose, or urea give this result. Remarkable glycerol effects on other fibrillar systems have been reported[3,4].

The work was based on the hypothesis that the spiralization caused by hypotony is a result of a flux of ions or other low-molecular substances into the medium, causing disturbances in the contraction–relaxation mechanisms. Present work in this field[5–7] indicates that these mechanisms are in close agreement with those in muscle.

Validity of the Species *Cirratulus norvegicus* Southern

DURING the course of an investigation into the ecology of the cirratulid worm, *Cirriformia tentaculata* (Montagu) it was noticed that the young of this animal were remarkably similar to the worms described by Southern[1] as being of the species *Cirratulus norvegicus*. Previous workers have not been eager to accept this species. Fauvel[2], for example, regarded the worm as a variety of *C. tentaculata*. Wilson[3], while not denying the existence of a separate species (since Southern reported a mature female), directed attention to the fact that the features used by Southern to distinguish *C. norvegicus* from *C. tentaculata* were in general those that might occur in the juveniles of the latter species.

The following characters are those by which Southern distinguished *C. norvegicus*: (*a*) it was of smaller size and had fewer segments; (*b*) there were fewer tentacular filaments and these were on the fourth chaetigerous segment, those of *C. tentaculata* being on the sixth or seventh; (*c*) the crotchets appeared on a more anterior segment.

Several hundreds of young stages of *C. tentaculata* were examined between December 1959 and December 1961. Of these, many possessed all the features ascribed to *C. norvegicus* by Southern. A young polychaete is of smaller size and has fewer segments than the adult, thus it is not difficult to explain Southern's first distinction. With regard to the other distinguishing characters, the data collected during the two-year period showed that very young *C. tentaculata* possess tentacular filaments and crotchets on the anterior chaetigerous segments. As the worms grow, the filaments and crotchets are progressively lost from the early setigers and replaced by others farther back. Clearly, during their development the animals must pass through a stage in which the tentacular filaments an crotchets are positioned as in Southern's *C. norvegicus*. I addition, specimens of *C. tentaculata* which have reache this 'identical stage' in their physical development ar sexually mature. Hence, it is not difficult to account fo the existence of the gravid female reported by Southern

It would appear, therefore, that the doubts expressed b Wilson as to the validity of the species *C. norvegicus* ar well founded, and the animals recorded by Southern wer only physically immature specimens of *C. tentaculata*.

Decay and Recovery of Luminescent Ability in *Gonyaulax monilata*

SOME species of dinoflagellates respond to mechanica stimuli by emitting visible light. When stimuli of constant intensity are applied at regular time-intervals progressively lower light-intensities result. This is caused by a temporary exhaustion of the bioluminescent system o the organisms. Recovery can be complete provided the organisms are permitted to rest for a suitable period o time. A mathematical model is proposed to describe the response of *Gonyaulax monilata* to mechanical stimuli of 1/2-sec duration occurring at regularly spaced time intervals. The results of measurements are compared with the mathematical model.

It is assumed that the intensity of luminescence produced on stimulation is proportional to the number of dinoflagellates, Σ, able to respond at the beginning of the time interval, and that during and after stimulation the ability to respond will be recovered at a constant rate. The net rate of recovery for the interval of stimulation is then given by $\frac{d\Sigma}{dt} = \gamma - \delta\Sigma$, where γ is the recovery constant and δ is the decay constant.

The solution of this equation yields, subject to the condition that:

$$\Sigma = \Sigma_0 \text{ at } t = 0, \quad \Sigma = \frac{\gamma}{\delta}(1 - e^{-\delta t}) + \Sigma_0 e^{-\delta t}$$

In investigating the validity of this expression, agreement between experiment and a mathematical model was improved by assuming a period of inactivity (14·5 sec) immediately following stimulation. Values of 0·04 and 0·14 were chosen for γ and δ respectively. The time-intensity relationship of luminescence was determined as follows: at $t = 0$, let $\Sigma_0 = 50$, an arbitrary value. The value of Σ is calculated for $t = 0·5$ sec. The next 14·5 sec are considered dead time, leaving 15 sec for recovery at the constant rate γ, for a 30-sec period. The recovery is added to the calculated value of Σ, giving the Σ_0 for the next period. This process is repeated in conformity

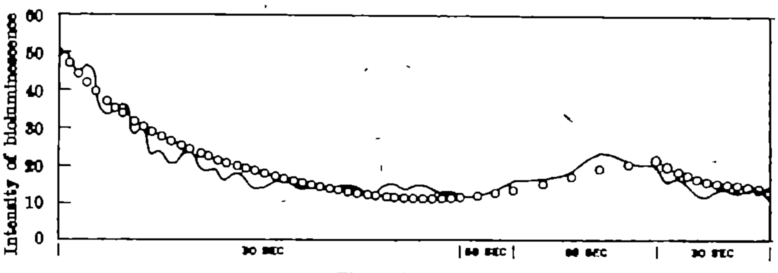

Fig. 1. —, Observed; ○, calculated

with the experimental procedure which includes 58- and 38-sec periods.

The observed and calculated responses are shown in Fig. 1.

No attempt was made to reproduce the fluctuations in the experimental curve. These are believed purely random and are consistent with variations in the observed responses of different cultures of *Gonyaulax monilata*.

We thank Dr. Giorgio Soli of the Naval Ordnance Test Station for the experimental data.

Cœnocytic Vessel Elements in *Dioscorea alata* L.

DURING the course of a morpho-histogenic study on the cultivated species of *Dioscorea* of Gujarat State, India, certain observations were made on the development of the vessel elements in the stem of *D. alata* (Kamodio variety). The vessel elements of the plant were found to be unusual in being very broad with long scalariform plates which often exhibit a branching of the bars in the plate[1,2].

The metaxylem vessel elements are 1·3 cm long, and have perforation plates varying from oblique, elongated and scalariform to transverse, rounded and reticulate. The tracheids are branched and show scalariform pitting. Intermediate types, such as vessel elements with only one perforation plate at one of the ends and 'vessel-tracheids', are also present. These latter are tracheid-like elements with a small perforation plate composed of a few branched and unbranched bars. It is doubtful if any membrane is present between them. The vessel-tracheids have small, simple, elongated pits on the other parts of the wall, and are obviously of a different category from those defined by Fahn[3].

The protoplast of the vessel element of *D. alata* is cœnocytic. As many as 7–9 or more nuclei were observed in vessel elements, 0·5 cm long. The multinucleate phase in vessel differentiation is due to divisions of the nucleus of the mother cell (Figs. 1 and 2). This contradicts Hill and Freeman's observations according to which the multinucleate condition in the central vessels of the root of *D. prehensilis* is due to an obliteration of the transverse and lateral walls of the elements[4]. The nuclei are scattered throughout the length of the vessel elements during the phase of elongation.

Later the protoplast becomes fragmented into disconnected strands. Pirotta and Buscalioni (1898)[5] and Němec (1910) reported that in the Dioscoreaceae the perforation of the end walls occurs after the disintegration of the nuclei; but in my material the cœnocytic protoplast has been found to persist even after the formation of the perforation plate (Figs. 3 and 4), which is most unusual. Eames and MacDaniels[6] and Esau[7] now suggest that in the development of the vessel the protoplast must persist at least until the completion of the perforation plate.

I thank Prof. P. Maheshwari for helpful suggestions and the University of Gujarat for supporting this work.

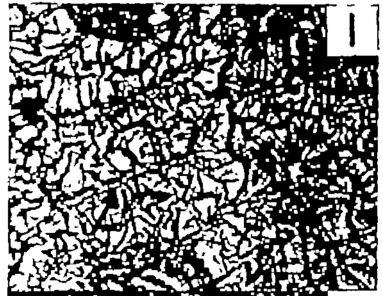
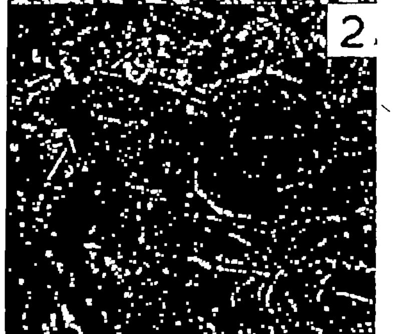
Reticulate Cuticle on Leaf Epidermis in *Hevea brasiliensis* Muell.

VARIATIONS of the surface patterns of cuticles have attracted the attention of both plant morphologists and physiologists. The formation and the functions of cuticle have been previously discussed[1-3]. Electron microscopic studies have revealed much greater details[4,5]. Observations under the light microscope show three main types of cuticles, namely, lamellate, striate and reticulate[1,6,7], and the effects of cell growth are mentioned as chief causes for the formation of different types[1,4]. Of these three, occurrence of the lamellate cuticle appears to be more common than the other two. Different genera that possess striated cuticles have been listed[3,7].

Martens[6,8] examined in detail the cuticle pattern on the floral parts of *Tradescantia*. In most instances he observed lamellate and striate cuticles and only in few cases the reticulate type. Scarcely any other report has been made about the occurrence of reticulate cuticle in plants. The present observations illustrate the occurrence and nature of reticulate cuticle on the lower epidermis in *Hevea brasiliensis*.

Leaves of *H. brasiliensis* were collected from plants growing in the University compound. Peels of upper and lower epidermis of leaves were made and observed under the microscope. Some of these were stained with 1 per cent safranin. Transverse as well as paradermal sections of leaves, 5–8µ thick, were prepared and stained with safranin and green. The cells of the upper epidermis, in the surface view, are angular in outline and covered with thick lamellate cuticle. Lower epidermal cells are wavy





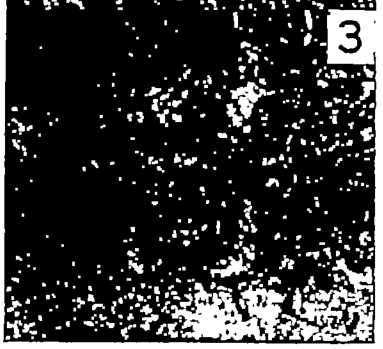


Fig. 1. Surface view of lower epidermal peel showing reticulate cuticle

Fig. 2. Paradermal section of epidermis showing central ridge and arms

Fig. 3. Transverse section of leaf showing a part of leaf with lower epidermis and cuticle. Arrows indicate the central ridges and their arms (× 200)

in outline. On each cell there is a thick ridge of cuticle, median in position and oriented parallel to the long axis of the cell (Figs. 1 and 2). From this central ridge several arms originate with gradual tapering ends. Some of these extend to the neighbouring cells and establish connexion with the main ridge and arms thereof, forming a loose reticulum (Fig. 1). In no instance were they observed to extend beyond the neighbouring cells. The refractive reticulum was best focused differently from the epidermal cells (Fig. 2).

The stomata are present only on the lower epidermal cells and are of paracytic type[9] (Fig. 2). The median ridge of cuticle was usually absent on the subsidiary cells and this was better evidenced in the paradermal sections (Fig. 2). In case of *Cestrum* it was noticed that the stomata were focii of origin for the development of striations[7]. In the present case, however, the ridge and the arms developed on all the epidermal cells except guard or subsidiary cells. The transverse section of the leaf shows the extracellular position of reticulate branches and superficially they resemble the fibrous thickenings of anther endothecium (Fig. 3).

Young leaves were also studied for developmental stages. Even a young leaf that measured 2·0 × 1·0 cm showed the formation of cuticular reticulum on its lower surface and it was more prominent near the midrib region than on the lamina. Leaves collected from different parts of Malaya were also examined. All of them possessed reticulate cuticle, which led to the suggestion that the formation of cuticle was not affected by environmental factors.

ENTOMOLOGY

Wild Pigs as Hosts of *Glossina vanhoofi* Henrard and *Trypanosoma suis* Ochmann in the Central African Forest

IN 1951 we found in *Glossina brevipalpis* from the Institute of Scientific Research in Central Africa's Mosso field station, Burundi, north-east of Lake Tanganyika, a trypanosome infection of the salivary glands similar to that noted by Burtt in 1942 near Amani, Tanganyika. Our rate of infection was very low; two infected flies out of 700 dissections of salivary glands (0·28 per cent) as compared with the low rates found also by Burtt (0·84 per cent), by Whitnall in 1934 (0·62 per cent) and by Brown in 1938 (1·14 per cent). Elsewhere we have stated[1] regarding the salivary gland infections that "we do not believe that this trypanosome is necessarily a polymorphic one as assumed by Burtt. Its morphology might be completely different from the trypanosomes of the salivary glands in *G. palpalis* and *G. morsitans*". As many as 6,397 *G. brevipalpis* were examined during the period April 1952–April 1953 by E. Peel and M. Chardome in our laboratory. They discovered 1·09 per cent infection of the salivary glands and isolated strains which when transmitted cyclically to domesticated pigs, showed a monomorphic trypanosome identical with *T. suis* Ochmann. This trypanosome was originally recorded in East Africa, first by Ochmann (1905) from the domestic pig, and later in 1912 by Geisler and Mayer from the warthog: all these authors gave an inadequate description of this trypanosome. Preparations showing *T. suis* from the Congo were demonstrated by L. van den Berghe[2] at a laboratory meeting of the Royal Society of Tropical Medicine and Hygiene in January 1954, and it was finally adequately described by Peel and Chardome in 1954[3] (preliminary announcement in 1953[4]) and its revival announced by Hoare the same year.

In 1955[1] we were fortunate in discovering in the Irangi dense forest station of the Institute of Scientific Research in Central Africa, west of Lake Kivu, Congo, a large fly belonging to the fusca group, *Glossina vanhoofi* Henrard, which was known as a museum species and had never been observed in its habitat. The study of the biology of *G. vanhoofi* proved very difficult in comparison with our previous field work with *G. brevipalpis* in the Mosso field station. The population of a forest species of *Glossina* seems far more dispersed than the one of a savannah fly. The limited range of visibility and the very poor light are also factors which rendered the discovery of *G. vanhoofi* particularly arduous in the dense Irangi forest. This fly very rarely feeds on man, another factor which makes it difficult to capture.

In the course of 1960 we were able to ascertain one important fact in the biology of *G. vanhoofi*. While for years we had never been able to discover more than one or two replete flies, we finally secured a few (six in all) gorged males from distant sites around the station. The stomach contents, sent to Weitz in London, demonstrated in all cases blood from wild pigs. *Potamochoerus* are common in the Irangi forest but *Hylochoerus* are also found in the region. It seems that the wild pigs of the forest are the preferred, if not the only, hosts of *G. vanhoofi*. This is in complete agreement with the findings made approximately at the same time (1952–55) by several authors studying the stomach contents of the *G. morsitans* group in the eastern savannah belts (Lovemore[5] in Southern Rhodesia, Weitz and Jackson[6] in Tanganyika, and van den Berghe and Lambrecht[7] in Rwanda). A *Potamochoerus* host preference was also established in West African forest (Nigeria) for *G. fusca*, *G. nigrofusca* and *G. medicorum*.

Infections of the salivary glands of *G. vanhoofi* had already been discovered by us in 1955, providing an identical picture to that found in the Mosso savannah region with *G. brevipalpis*. *T. suis* Ochmann was identified in the laboratory at Lwiro from stained metacyclic forms[8] and its geographical distribution, therefore, considerably extended from the East African savannahs to the dense central African forest.

The investigations were made at the Laboratory of Medical Protozoology and Zoology, Institute of Scientific Research in Central Africa, Lwiro (Bukavu), Congo, and at its forest station (Irangi, Maniema).

MICROBIOLOGY

Nitrification by *Arthrobacter globiformis*

A VARIETY of heterotrophic micro-organisms have now been shown to effect the biological oxidation of nitrogen. Bacteria and actinomycetes have been reported to produce nitrite in the presence of ammonia[1,4], pyruvic oxime[2,3,5], and ethylurethane[6,7]. The fungus, *Aspergillus flavus*, produces hydroxylamine, nitrite and nitrate from ammonia or amino compounds[8,9]. The ecological significance of heterotrophic nitrification in complex natural environments has, however, been viewed with some reservation[10]. The observation reported here that a strain of *Arthrobacter globiformis*, a ubiquitous soil inhabitant, oxidizes ammonia to hydroxylamine, nitrite, nitrate, and possibly a gaseous intermediate may, therefore, be of some ecological interest.

A. globiformis strain 616 was used in these investigations. It was grown in a medium containing, per litre distilled, de-ionized water: NH_4Cl, 2·0 g; KH_2PO_4, 1·0 g; K_2HPO_4, 1·5 g; $MgSO_4.7H_2O$, 0·6 g; iron chelate[11], 4·0 ml; $ZnSO_4.7H_2O$, 0·03 g. Succinic acid was the sole source of carbon; it was provided in the form of a succinic acid–sodium hydroxide buffer, *p*H 6·2, separately sterilized by Seitz filtration and added so as to give a final concentration of 0·05 M succinate. The final *p*H of the medium was 6·9–7·0. Culture vessels were vigorously aerated with sterile air, and incubated for 21 days in a water bath maintained at 28° C.

Resting cells were obtained by centrifuging 18-h cultures at 27,000*g* in a continuous flow centrifuge (Ivan Sorvall, Inc., Norwalk, Conn.). The supernatant was discarded and the cells washed twice in 0·2 M hydrochloric acid–*tris*(hydroxymethyl)aminomethane (*tris*) buffer, *p*H 7·2. Tests for the presence of hydroxylamine, nitrite and nitrate in the final wash solution were negative. The cells (35–40 mg dry weight) were rinsed out of the centrifuge tubes with 10 ml. of a substrate consisting of the *tris* buffer and 0·01 M $(NH_4)_2HPO_4$, 50 per cent v/v, *p*H 7·2. This cell-substrate suspension was transferred into duplicate 25 × 150-mm test-tubes, and vigorously aerated. The gases from each reaction tube were exhausted through a separate trap containing 10 ml. distilled, de-ionized water, or 10 ml. freshly prepared Griess-Ilosvay reagent[12]. The latter served as an indicator for the formation of any gaseous nitrogen oxide in that a red colour was produced proportional to the nitrous acid concentration. Oxides of nitrogen formed in the reaction tubes were also absorbed in separate traps containing 40 ml. of absorbing solution (35 ml. of 5 per cent potassium hydroxide solution and 5 ml. of 3 per cent hydrogen peroxide). The hydrogen peroxide ensured that all the oxides were in the nitrate form. Reagent tubes and traps were incubated up to 36 h in a water bath at 28° C. Uninoculated controls were maintained for each treatment. All glassware was acid washed.

Analyses for ammonia were made colorimetrically[13]. Protein was measured with Folin phenol reagent[14]. Hydroxylamine was determined by iodine oxidation[15]. Nitrite was estimated by the α-naphthylamine sulphanilic acid procedure. Nitrate was measured by the phenol–disulphonic acid method or by the Middleton technique[16].

The results shown in Table 1 are typical of those obtained with actively growing cultures.

Table 1. PRODUCTION OF HYDROXYLAMINE, NITRITE AND NITRATE BY GROWING CULTURES OF *Arthrobacter globiformis**

Product	μg N/ml.
Hydroxylamine	0·20
Nitrite	0 20
Nitrate	4 50

* Culture sampled after 5 days' incubation.

Results obtained with resting cells are shown in Table 2.

Table 2. PRODUCTION OF HYDROXYLAMINE, NITRITE AND NITRATE BY RESTING CELLS OF *Arthrobacter globiformis* after 24 H

Product	μg N/ml.
Hydroxylamine	0·05
Nitrite	1·50
Nitrate	1·00

At the termination of experiments with resting cells the products of ammonia oxidation together with the residual ammonia generally accounted for only about 80 per cent of the initial substrate. Analysis of the cells showed no increase in protein, suggesting that gaseous oxides of nitrogen might have been produced and lost through volatilization. In such an event it was anticipated that at least traces of such gas, or gases, would be swept over by means of the vacuum line used to aerate the system from the reaction tube into the trapping tube. Analyses of both the distilled water and the Griess-Ilosvay reagent in respective traps showed amounts of NO_2^- present in the order of 0·15 μg per ml. An attempt was made to identify the gas produced by treating the Griess-Ilosvay reagent with pure nitrous oxide and pure nitric oxide (The Matheson Co., Joliet, Ill.). Only nitric oxide gave a colour reaction corresponding to that obtained experimentally. Analysis for nitrate in the potassium hydroxide–hydrogen peroxide solution, however, gave a somewhat higher result, 0·5 μg NO_3^- per ml., suggesting that the production of some other gaseous nitrogen oxide could not be ruled out.

Of immediate interest, however, is the evidence suggesting that the genus *Arthrobacter* may be implicated in nitrification; moreover, it may be included among those few select genera reported capable of oxidizing nitrogen to nitrate. It is also of interest that in the oxidation of ammonia by *A. globiformis* gaseous nitrogen oxides are produced. The formation of these compounds suggests that nitrogen losses may occur through oxidative as well as reductive processes. In all these instances the relatively small experimental recovery may none the less be of considerable ecological and practical significance because of the large numbers of *Arthrobacter* in the soil[17].

GENETICS

Inheritance of Serum Transferrins in Rhesus Monkeys

AN extensive polymorphism of transferrin, the iron binding protein of plasma, has been detected among rhesus monkeys and other macaques[1-4]. In previous work[5], 19 phenotypes due to different combinations of nine molecular forms of transferrin could be distinguished by starch-gel electrophoresis. Additional transferrin variations have now been discovered (Goodman, M., unpublished data), and there are at least 28 phenotypes and 11 molecular forms of transferrin present in the genus *Macaca*, the rhesus group alone showing 21 of these phenotypes and 9 of these transferrins.

The macaque transferrin of slowest electrophoretic mobility has been labelled[6] A and that of fastest mobility, H. (H^1 migrates between G and H, the newly discovered F^1 between E and F, and E' between D and E.) Typically a sample of macaque serum contains either one or two molecular forms of transferrin. Thus we can suppose that the observed transferrin variation is due to an allelic series of genes and that phenotypes such as CC consisting of a single transferrin are controlled by homozygous combinations of genes, whereas those such as CD consisting of two transferrins are controlled by heterozygous combinations.

In order to investigate the inheritance of macaque transferrins, we determined by comparative one-dimensional starch-gel electrophoresis in the *tris* discontinuous buffer system[6] the transferrin phenotypes of rhesus monkeys in the breeding colony of the Primate Laboratory of the University of Wisconsin. The results are presented in Table 1. It can be seen that the four offspring of the $CC \times CC$ matings were all phenotype CC. (In the breeding colony, as in the rhesus monkeys from the Nepal border of India[5], the most frequently occurring transferrin type was C.) There were 6 offspring of $CC \times CG$ matings; 4 were phenotype CC and 2 were CG. The 2 offspring of $CG \times CG$ were CG and GG respectively. The 1 offspring of $CD \times CD$ was DD. The 2 offspring of $CF \times CC$ were CC and CF respectively. Finally, 1 offspring of $CD \times CG$ was DG and another offspring originally attributed to the same mating combination was CH. Thus with the exception of monkey 62 (the offspring with CH phenotype) each offspring always had one transferrin identical in type to one of the mother's and one transferrin identical in type to one of the father's. A re-check of the records of 270, the mother of 62, raised doubt that R–16 (a male with CG phenotype) was the sire of 62 in that the date of access of R–16 to 270 could not account for the pregnancy of the latter. Nor did the records show which male could be implicated.

Table 1. TRANSFERRIN PHENOTYPES OF PARENTS AND OFFSPRING IN A BREEDING COLONY OF RHESUS MONKEYS

Designation of animal			Transferrin phenotype		
Mother	Father	Offspring (sex)	Mother	Father	Offspring
R–3	R–6	32 F	CC	CC	CC
299	R–2	81 F	CC	CC	CC
69	R–2	75 F	CC	CC	CC
69	R–2	100 F	CC	CC	CC
248	R–16	49 F	CC	CG	CC
R–15	R–16	61 F	CC	CG	CC
R–11	R–16	71 M	CC	CG	CC
296	R–16	43 M	CC	CG	CC
R–55	R–6	83 M	CG	CC	CG
302	R–2	A–25 F	CG	CC	CG
292	R–16	35 F	CG	CG	GG
302	R–16	57 M	CG	CG	CG
281	R–64	A–75 F	CD	CD	DD
310	R–6	33 F	CF	CC	CC
310	R–6	82 F	CF	CC	CF
270	R–16	30 M	CD	CG	DG
270	(R–16?)	62 F	CD	(CG?)	CH

Discounting the transferrin results for 62, our results support the hypothesis that an allelic series of genes at a single locus controls the variation of transferrin types in rhesus monkeys, with each gene responsible for a particular transferrin and with no gene in the allelic series having dominance over another. However, the earlier anomalous finding[4,5] of a rhesus monkey serum with three molecular transferrin types (BDG) suggests that a more elaborate genetic hypothesis may be needed to account for the full complexity of the transferrin polymorphism of rhesus monkeys.

We thank Dr. Gabriel W. Lasker for his advice on the genetic significance of the data.

Size in Relation to Development-time and Egg-density in *Drosophila melanogaster*

A RECENT report by Wattiaux[1] emphasizes the importance of speed of development in relation to the expression of a quantitative character in *Drosophila melanogaster*, namely bristle number. Using another such character, size of thorax, I investigated the ubiquity of the disclosed relationship. However, different sets of environmental conditions, bearing on temperature and egg density (or larval crowding), were introduced in order to test its eventual variation.

A given number of flies of a wild-strain, Abeele (Belgium), aged 7 days, and hatched after an equal duration of development, were allowed to lay during a 4-h period, at 25° C, on an agar–acetic acid medium. The eggs were redistributed by lots of 30 or 240 per standard tube, and placed in three controlled-temperature chambers, at 18°, 25° and 29° C (± 0·1° C). At each temperature, 24 replicates were made for the density 30 and 6 for the density 240. Flies emerging at 29° and 25° C were scored and sexed twice, and those at 18° C once, daily. In each consecutive 12- or 24-h hatching group the totality or a sample (maximal 30 flies) of females and males was measured for thorax-length following the usual technique[2]. Figs. 1 and 2 show the results of this series of measurements. Table 1 gives the correlation coefficients development time-size (Spearman's correlation), the mean size and the viability of each temperature-density combination considered.

Table 1. SIZE-DEVELOPMENT TIME CORRELATION, SIZE, VIABILITY PERCENTAGE IN THE DIFFERENT TEMPERATURE–EGG DENSITY COMBINATIONS USED. A THEORETICAL 1 : 1 SEX-RATIO IS SUPPOSED IN THE VIABILITY CALCULATIONS FOR MALES AND FEMALES

	30 eggs		240 eggs	
	♀♀	♂♂	♀♀	♂♂
	Spearman's correlation coefficient			
29° C	—1·00*	—1·00*	—0·64	—0·30
25° C	—0·94*	—1·00*	0·23	0·05
18° C	—0·98*	—0·95*	—0·60†	—0·24
	Size			
29° C	38·7 ± 0·17	34·2 ± 0·13	33·4 ± 0·14	30·1 ± 0·15
25° C	40·4 ± 0·16	36 0 ± 0·15	34·3 ± 0·12	30·3 ± 0·11
18° C	41·2 ± 0·13	37·1 ± 0·14	37·7 ± 0·11	33·9 ± 0·10
	Viability			
29° C	60·3	52·8	47·3	44·0
25° C	76 1	73·6	70·0	57·9
18° C	81·1	81·7	61·9	56·9

* $P < 0·01$
† $0·01 < P < 0·05$

The main results are as follows:

(1) With an original density of 30 eggs a tube (Fig. 1), size, expressed as mean size for each 12- or 24-h group, decreases regularly as development time increases; the correlation coefficients are highly significant (P always $< 0·01$). The percentage decrease from the first to the last day of emergence is quite different for both sexes, varying between 7·1 and 9·5 per cent for males and 9·6 and 13·3 per cent for females. Temperature does not seem to influence this decrease.

(2) With an original density of 240 eggs a tube (Fig. 2) there is no relationship between prolongation of the development time and size, except for 18° C females showing a decrease of 5·4 per cent between the extremes.

(3) There is a relatively slight difference in viability between the two population densities. Of course, viability is always inferior at 240, the difference varying from ± 11 per cent at 29° and 25° to ± 22 per cent at 18° C. Supposing a 1:1 primary sex-ratio, the mortality rate is always higher for males (Table 1).

Three different hypotheses may be invoked on to explain the results:

(*A*) *Environmental modification of identical genotypes*. This hypothesis is implicit in Gordon and Sang's examination[3] of the modifications of a staling medium, and was considered by Wattiaux[1] as an explanation for the variation of bristle numbers in relation to speed of development. This hypothesis can be discarded, for it does not account for the size constancy observed in the high population density, where the influence of a staling medium, the duration of emergence being longer, should be acting at a maximum.

(*B*) *Differential selection*. Although the slight differences in viability between temperature and density groups render a hypothesis based on differential survival very questionable, it can be imagined that, especially and only at low densities, genotypes for high developmental rate and large size would survive. Since up to this moment the crucial evidence concerning the heritability of the different size-rate combinations is lacking, it seems useless to discuss the possibilities offered by classical polygenic models, based on pleiotropy[4], or on linkage for both characters[5], or on differential selection for heterozygotes versus homozygotes in given environmental sets[6].

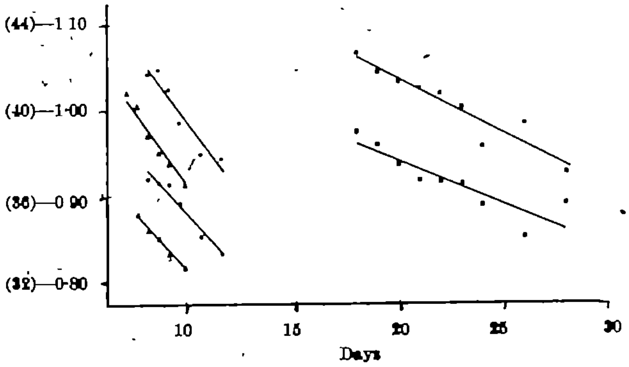

Fig. 1. Relation between size and duration of development at three temperatures and an original density of 30 eggs per tube. Duration of development is expressed in days from the egg-laying; size in arbitrary units (between brackets) and mm. 29°, ▲, ♀♀, △, ♂♂, 25°, ● ♀♀, ○, ♂♂; 18°, ■, ♀♀, □, ♂♂

(*C*) *Differential environmental effects on different genotypes*. Although this hypothesis requires the same crucial heritability demonstration, it seems *a priori* the most economical and simple one. It would mean that, in all experimental conditions, a population of the same average genotypical constitution for rate and size survives. However, only at low densities do different genotypes determine jointly the complete array of phenotypes from large-sized, rapidly developing flies to small-sized, slowly developing ones. It would be expected for nutritional reasons that at high densities the large body size, normally accompanying rapid development, does not reach expression. The relatively low expression of large body size at low densities and high temperatures can be explained on a similar basis.

As a partial and indirect confirmation of the last hypothesis, it must be remembered that it was possible to show repeatedly that the plus or minus sign and the significance of the size-development time correlations depend on the environment (temperature, density, culture medium)[7,8] and on the genetic nature of the strain[9]. Using the same wild-strain and an explanation based on this hypothesis, it was also possible to account for the failure of size ranges to coincide according to diverse temperature-density sets[9].

Whatever results are obtained in future experiments with respect to the morphogenetic relationship between size and time for development, and to the nature of the possible population genotypic variance with respect to

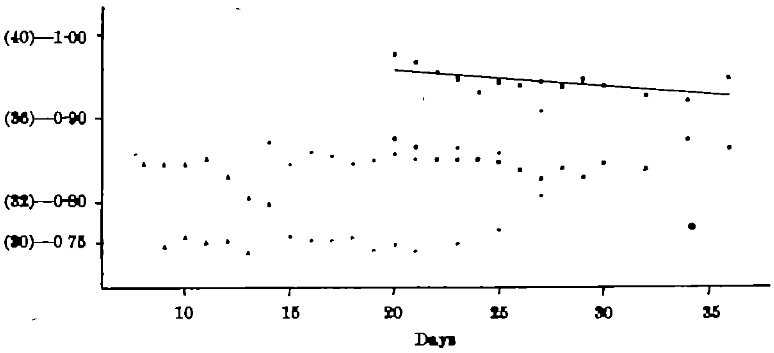

Fig. 2. As in Fig. 1 for an original density of 240 eggs a tube. Symbols same as Fig. 1

that relationship, present results emphasize the necessity of introducing into experiments concerning quantitative characters an array of controlled environmental conditions. Wattiaux's experiments and the present ones call, on the other hand, for a more thorough study of such a quantitative trait as rate of development, which possibly determines, directly or indirectly, and in a way depending on environmental conditions, many others; they should be considered as a first step, that of establishing the exact relationship between quantitative characters and development time, before scrutinizing the relationship of parental duration of development and the characters of the offspring.

Effect of Grafting on the Incompatibility Response of *Oenothera organensis*

POLLEN-STYLE compatibility in *Oenothera organensis* is determined by a series of allelic genes designated S_1S_2, S_3S_4, etc.[1]. S_1 or S_2 pollen on an S_1S_2 stigma germinates but penetrates the style only a few millimetres. S_3, S_4 . . . S_n pollen on S_1S_2 grows through the entire length of the style (about 150 mm), reaching the ovary in a 12-h period. (Plants derived from the original Emerson[1] collections have retained their high degree of self-incompatibility. These collections were made in 1937 at a time when the population of *O. organensis* in this type location (Dripping Springs, Organ Mountains, New Mexico) was estimated to be more than 100 plants. A subsequent collection made in 1959 by Drs. S. Emerson and R. S. Bandurski has proved to have a much higher degree of self-fertility. At the time this later collection was made, the number of individuals in the type locality had been reduced to about 8 plants. It thus appears that the population became at least partially self-fertile as the plant neared extinction.)

Many lines of evidence indicate that pollen-style incompatibility is caused by an immune response of the type commonly associated with higher animals. For example, by labelling of the sexual partners with phosphorus-32 and carbon-14, followed by isolation of proteinaceous compounds formed during inhibited growth, Linskens[2,3] demonstrated that a "glycoproteid" was formed by both participants in incompatible matings which differed from that normally present. Serological tests with extracts from pollen and stylar tissue of *Oenothera organensis*[4] and *Petunia* hybrids[5] show that the homologous reaction is stronger than the heterologous one.

Demonstration that incompatibility in *Petunia* can be eliminated by ionizing radiation[6] is also in keeping with the suggestion of an immune response and further supporting evidence is provided by the observation of protoplasmic clumping following micro-injection of *Neurospora crassa* hyphae with cytoplasm from incompatible strains[7].

In this communication we report an effect of grafting on the incompatibility response of *Oenothera organensis* in which a partial tolerance to normally incompatible pollen is temporarily established. Several previous reports of lowered incompatibility in plants following grafting have appeared[8-10], and a recent report shows a temporary loss of tissue transplant immunity in parabiotic birds[11].

Plants of the same or differing allelic constitution grown from cuttings of non-grafted stocks were approach-grafted and kept in a greenhouse at 17° C night and varying day temperature. The plants were flowering at the time grafts were made. A photoperiod of at least 13 h was maintained. Graft unions were formed in a week and well established in two to three weeks. An adaptation of the technique of Emerson[1] was used to determine pollen-style compatibility. Flower buds were detached just prior to opening, emasculated and heavily pollinated. After a 24-h growth period at 25° C and 80 per cent relative humidity the styles were fixed and stained in an alcoholic solution of iodine in potassium iodide (iodine, 1 g; potassium iodide, 15 g; 30 per cent alcohol, 100 ml.). Pollen tube penetration can then be measured under the microscope in segments of the crushed stylar tissue. Results obtained with detached flowers were found to be the same as corresponding pollinations of flowers left attached to the plants. Five experiments of at least two pairs of plants of each graft-combination were performed.

Pollen-style incompatibility was determined at weekly intervals during the period zero to ten weeks following grafting. Results of the average of two typical experiments are presented in Fig. 1. As can be seen the ungrafted control S_1S_2 is self-sterile and pollen tubes do not penetrate the style when the plant is self-pollinated. The cross, S_1S_2/S_3S_4, is, of course, fertile and pollen tubes penetrate the entire stylar length. A further control is provided by an S_1S_2 plant grafted to an S_1S_2 plant. This graft has no effect on pollen tube growth. When, however, an S_1S_2 plant is grafted to S_3S_4 then, within 2–3 weeks following grafting, S_1S_2 pollen from an ungrafted plant will penetrate the S_1S_2 stylar tissue of the grafted parent. This result shows that grafting affects the immune response of the stylar tissue. The effect of grafting on S_1S_2 plant to S_3S_4 and then self-pollinating is greater than that seen when the pollen was from an ungrafted plant, suggesting that grafting also diminishes the immune response of the pollen. That this is the case is shown by the experiment of Table 1. In this experiment, again the average of two experiments, it can be seen that pollen from an S_1S_2 flower of an S_1S_2 plant grafted to S_3S_4 penetrated the style of an ungrafted S_1S_2 plant. Thus the effect of grafting on the pollen response is demonstrated. This effect is, however, delayed by 2–3 weeks and is one-third to one-half as strong as evidenced by an S_1S_2 plant grafted to S_3S_4 and self-pollinated.

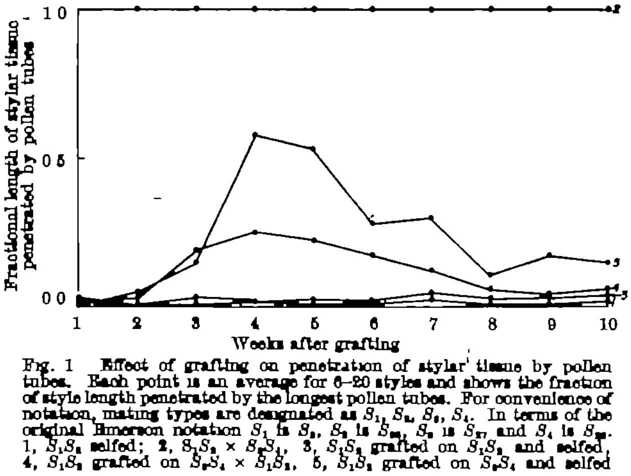

Fig. 1 Effect of grafting on penetration of stylar tissue by pollen tubes. Each point is an average for 6–20 styles and shows the fraction of style length penetrated by the longest pollen tubes. For convenience of notation, mating types are designated as S_1, S_2, S_3, S_4. In terms of the original Emerson notation S_1 is S_3, S_2 is S[illegible], S_3 is S_{17} and S_4 is S[illegible]. 1, S_1S_2 selfed; 2, $S_1S_2 \times S_3S_4$; 3, S_1S_2 grafted on S_1S_2 and selfed, 4, S_1S_2 grafted on $S_3S_4 \times S_1S_2$; 5, S_1S_2 grafted on S_3S_4 and selfed

Several conclusions may be drawn from data here reported. It is apparent that the incompatibility response involves both stylar and pollen factors since heterologous grafting of either the pollen or stylar parent diminishes the incompatibility response. In addition, since seed is not set following self-pollination of heterologously grafted plants (although pollen tubes have been observed to grow to the carpel) it may be concluded that there is a second barrier to self-fertilization. These conclusions are con-

Table 1. FRACTIONAL LENGTH OF STYLAR TISSUE PENETRATED BY POLLEN TUBES*

Graft-combinations pollinated	Weeks after grafting 1	2	3	4	5	6	7	8	9	10

VIROLOGY

Isolation from Man in Slovenia of a Virus belonging to the California Complex of Arthropod-borne Viruses

FOLLOWING observations[1] that in some areas of Slovenia, Yugoslavia, inapparent infections with Central European tick-borne encephalitis virus are common, attempts were made to isolate this agent from clinically inapparent but serologically detectable infections. In the course of this work two strains of another arthropod-borne virus were obtained. Designated Trojica Nos. 1 and 2 after the village where they occurred, these strains have now been identified as belonging to the California complex[2] of arthropod-borne viruses.

The isolations were made from two sera of about 5,000 collected from healthy human beings during the spring and summer of 1960 and 1961 in different localities in Slovenia known as endemic foci of Central European tick-borne encephalitis.

Serum collections were stored for 1–5 weeks at −20° C before being used for virus isolations. About half the specimens were tested individually, the remainder in pools of two or three. Sera were filtered through Seitz *EK* pads and centrifuged at 40,000 r.p.m. for 1 h. Sediments were resuspended in a volume of borate buffer, *p*H 7·2, between 1:10 and 1:20 of the original volume of the serum and inoculated into human embryo kidney cell cultures, chorioallantoic membranes of 12-day-old chick embryos and new-born mice.

Two sera that were pathogenic only for new-born mice yielded agents that could be serially propagated. Re-isolation from the original material kept at −20° C was successful in both cases.

The two strains had similar properties. By intracerebral or intraperitoneal inoculation they were pathogenic for new-born but not adult mice. They were sensitive to ethyl ether and sodium deoxycholate and were not neutralized by immune sera for several agents belonging in groups *A* and *B* of the arthropod-borne animal viruses.

The strains were also poor hæmagglutinin producers. A titre of 1:64 at *p*H 6·0 was obtained on one occasion with a new-born mouse brain antigen from strain No. 1, but this observation could not be repeated. After seven consecutive daily intracerebral passages in new-born mice, antigens with a titre of 1:10 at *p*H 6·0 and 6·1 were obtained. Both strains could be propagated in HeLa cell cultures, and by concentration of the fluid phase with an *LKB 6300A* ultrafilter[3], strain No. 1 yielded a low-titre hæmagglutinating antigen.

The strains were identified as belonging to the California complex in a complement-fixation test. Immune sera against both were prepared in adult mice given four intraperitoneal injections of a 10 per cent suspension of live virus. Antigens were prepared by acetone precipitation of a suspension of infected new-born mouse brain tissue in isotonic sucrose.

Neither serum reacted with complement-fixing antigens for the following viruses: eastern and western encephalitis, Semliki forest and Sindbis (group *A*); dengue type 2, Ntaya, Murray Valley encephalitis, Japanese *B* encephalitis, Central European tick-borne encephalitis, Russian spring–summer encephalitis, West Nile, yellow fever, St. Louis encephalitis and Zika (group *B*); and Guaroa, Simbu, Germiston, Bwamba, Chittoor and Neapolitan and Sicilian sandfly fevers. Both sera, however, had antibodies against California encephalitis and Tahyna antigens (Table 1).

Table 1. TITRES OF COMPLEMENT-FIXING ANTIBODIES IN IMMUNE SERA FOR TROJICA STRAINS NOS. 1 AND 2

Antigen	Serum Trojica No. 1	Trojica No. 2
California	16/8*	32/8
Tahyna	8/16	16/8
Trojica No. 1	16/16	32/8
Trojica No. 2	16/8	16/8

* Reciprocal of serum titre/reciprocal of antigen titre

The isolation of the Trojica strains is of interest, because viruses of the California complex have thus far been isolated from mosquitoes in several parts of the world but not from man. Thus, California encephalitis virus was obtained from *Aedes dorsalis* and *Culex tarsalis* in the United States[4], Lumbo from *Aedes pembaensis* in Mozambique[5], Tahyna from *A. vexans* and *A. caspius*[6,7] in Czechoslovakia, Trivittatus from *A. trivittatus* in the United States[4] and Melao from *A. scapularis* in Trinidad and Brazil[8]. Isolation of strains of this complex from man was not unexpected, however, since Bardos and Sevcoviceva[9] have reported the presence of Tahyna neutralizing antibodies in 8 per cent of 50 sera investigated from Slovenia.

Whether the two Trojica strains represent a new virus of this complex or a strain of one of the members already described—perhaps Tahyna—cannot be stated at the moment.

Bacterial Origin of Certain Viruses: Identity of the Eaton Agent with *Streptococcus MG*

In a recent communication Pease and Bisset[1] have given evidence in support of a hypothesis for the origin of myxoviruses from mucous-membrane parasitic bacteria, among other things, from the circumstances attending virus pneumonia (*PAP*). This condition, although ostensibly caused by a virus (or mycoplasma[2]), is accompanied by the development of serum agglutinins against a bacterium, *Streptococcus MG*, in a significant number of patients. Although the *Streptococcus* can sometimes be isolated from cases of the disease, attempts to demonstrate an antigenic relationship with the Eaton agent have previously failed[3].

I have now shown that antigenically active surface material is produced by the Eaton agent but is lost by diffusion into the medium, as is known to occur with bacterial *L*-forms[4], and this material, either *in situ* in a gel-diffusion test, or in the form of an extract, gives a strong positive precipitin reaction with *Streptococcus MG* antiserum. The material is apparently similar to the *M* protein of *Streptococci*.

Thus, the development of agglutinins in virus pneumonia patients, and the failure of previous efforts to establish an antigenic link, capable of accounting for the phenomenon, are simultaneously explained. At the same time, this observation provides an illustration of a pathogenic, virus-like agent that gives every evidence of being, in fact, the *L*-form of a bacterium. Indeed, here a strain of the Eaton agent has actually dissociated to give a bacterium resembling *Streptococcus MG*.

SOIL SCIENCE

Paper Electrochromatography of Clay Minerals

A major handicap in the study of clay minerals from soil systems is the lack of adequate methods for separating and quantitatively estimating individual minerals from clay mineral mixtures. Present success in the application of paper electrophoresis and paper chromatography to the study of complex organic mixtures suggests that such techniques also might prove promising in clay mineral studies. Although appearing theoretically promising, past electrophoresis studies of clay mineral suspensions have seemed to possess rather limited applicability[1-4]. Difficulties in obtaining and maintaining clear-cut separations of mineral mixtures have continually hampered clay mineralogists using such techniques. In an attempt to provide an improved technique for the separation and characterization of clay minerals from mineral mixtures, preliminary studies were undertaken on behaviour of the minerals under varying conditions of paper electrochromatography.

Minerals were located on dried filter paper curtains through the use of a 0·004 per cent solution of malachite green in nitrobenzene[5]. The stain was sensitive to as little as 1 μg of each mineral when used in the virtual absence of residual glycerol. Minerals were obvious as blue areas once the background of the surrounding paper had faded to its original white colour.

Conditions found during the initial series of experiments which permitted differential migration of clay minerals included the use of a Schleicher and Schuell 470-*A* paper curtain, with an electrolyte of 0·01 per cent sodium carbonate in a 20 per cent glycerol aqueous media (pH 9·6). A temperature of 8° C was maintained through the use of a water-cooled fractionation surface on which the curtain rested (Karler-Misco Electrochromatography Apparatus, Microchemical Specialties Company, Berkeley, California). Suspensions of less than 2μ reference minerals (0·01 per cent with respect to each mineral) were fed on to the curtain from a motor-driven syringe at the rate of 25 μg of each mineral per h.

Under the foregoing conditions, and with a potential gradient of 20 V/cm, bentonite was separated from a mixture with kaolinite and commercial vermiculite-like material in 48 h. The bentonite migrated diagonally toward the drip points on the anode side of the curtain (following the migration path previously demonstrated for reference montmorillonite): the kaolinite and vermiculitic material descended almost vertically with chromatographic buffer flow toward the drip points directly beneath the point of application (approximately 2 in. from the cathode side of the curtain).

Identity and integrity of minerals that had been subjected to electrochromatographic forces for a period of 72 h were checked by recovering sufficient quantities of the eluted minerals for X-ray analysis. Fractions from each of the 22 drip points were concentrated, the flocculent (glycerol saturated) spotted on glass slides, and the samples analysed with an X-ray diffractometer. Characteristic peaks for montmorillonite (18–19 Å), vermiculite (14 Å), and kaolinite (7 Å) were obtained in residues from drip points where migration paths of the previous experiments indicated these minerals would appear. The vermiculitic material appeared concentrated on the anode side of the kaolinite–vermiculite band, but apparently its migration was not sufficient to separate it from the non-migrating kaolinite. The separation into two bands was sufficiently clear-cut, however, to lend considerable support to the premise that electrochromatography or similar approaches may ultimately provide the means for the separation of at least simple clay mineral mixtures into their individual mineral components.

Adsorption of sample particles on supporting media, such as filter paper, has often been a major limitation in the application of paper electrophoresis to colloidal organic particles. In this series of experiments, strong adsorption of clay minerals on the paper resulted in slow migration speeds, tailing from the origin, and considerable broadening of the migration bands through diffusion. Such equipment difficulties might be resolved in the future by using less adsorptive supporting media or higher potential gradients.

More efficient apparatus, supporting media, and experimental conditions than were available for the present tests can undoubtedly be found. A modified Svensson and Brattsen apparatus, referred to by Mackenzie and Farquharson[6], may be more readily adaptable to macroscale mineralogical separations. (Some success with such an apparatus has been indicated by Mackenzie, personal communication, September 1961.) It is hoped that interest in this area will be stimulated such that efficient equipment will be developed and operating conditions defined for rapid separation and quantitative estimation of clay minerals by electrochromatographic techniques.

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. J. T. M. Taylor: "Research on Ground Control and Rockbursts on the Kolar Gold Field, India"; Mr. G. J. Brittingham: "Study of the Possible Application of Mineral Dressing Techniques for the Recovery of Uranium from the Conglomerates of the Serra de Jacobina, Bahia, Brazil".

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. Isabella Gordon: "The Role of Sound in Marine Biology"; Dr. P. J. Newbould: "Conservation and Biological Production".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. P. Erdos: "Problems and Results in Set Theory".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, W.C.1), at 6 p.m.—Mr. C. Hobbs: "Concrete Additives in the Building Industry from the Viewpoint of the Large Contractor".

Television Society (at 164 Shaftesbury Avenue, London, W.C.2), at 7 p.m.—Mr. Donald Wilson: "Writing for Television".*

Royal Society of Tropical Medicine and Hygiene (at the Royal Army Medical College, Millbank, London, S.W.1), at 7.30 p.m.—Laboratory Meeting.

Thursday, March 21—Friday, March 22

Institution of Mechanical Engineers, Education and Training Group (at 1 Birdcage Walk, Westminster, London, S.W.1)—Conference on "The Education and Training of Technicians".

Friday, March 22

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Discussion of Papers.

Royal Aeronautical Society, Man Powered Aircraft Group (at 4 Hamilton Place, London, W.1), at 6 p.m.—Mr. B. C. Clear-Hill and Mr. J. C. Wimpenny: "The Problems of Man Powered Flight".

Society of Chemical Industry, Plastics and Polymer Group (joint meeting with the South Wales Section of the S.C.I., at University College, Cathays Park, Cardiff), at 7 p.m.—Dr. I. Goodman: "Newer Knowledge of the Chemistry of Terylene and Related Polyesters".

Society for Visiting Scientists (at the English-Speaking Union, Dartmouth House, 37 Charles Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Evolution in Society". Chairman: Prof. C. D. Darlington, F.R.S. Speakers: Mr. T. Burns, Prof. V. C. Wynne-Edwards and Prof. Marc Klein.

Monday, March 25

Royal Society of Medicine, Library (Scientific Research) Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Mr. H. Palmer: "The Pharmaceutical Industry—What it is and What it Does".

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. John D. Woods and Mr. Brian B. Matthews: "Archæology Under the Sea".

Monday, March 25—Wednesday, March 27

Institution of Electrical Engineers, Electronics Division (at Savoy Place, London, W.C.2)—Convention on "H.F. Communication".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (preferably with some interest in the thermodynamics of co-ordination compounds) in Inorganic Chemistry—Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (March 22).

Lecturer (with special interests and qualifications in mineralogy and petrology) in Geology in the Faculty of Science—The Registrar, The University, Manchester 13 (March 23).

Senior Lecturer or Lecturer in Statistics; and a Lecturer in Pure Mathematics—The Secretary, The University, Northcote House, The Queen's Drive, Exeter, Devon (March 23).

Reader (with considerable research experience and the capacity to supervise postgraduate research students) in Botany—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (March 25).

Assistant in Genetics—The Secretary of University Court, The University, Glasgow (March 30).

Lecturer in the Department of Metallurgy—The Registrar, The University, Liverpool, quoting Ref. CV/270/N (March 30).

Lecturer, Senior Lecturer or Associate Professor in Applied Genetics at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 31).

Lecturers (2) in Computing—The Deputy Registrar, The University, Birmingham 15 (March 31).

Senior Lecturer (with special qualifications in analysis, preferably functional analysis) in Pure Mathematics—Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (April 1).

Lecturer (with experience of cultivation and processing of tropical crops, and of field experimentation) in Crop Husbandry in the Department of Agriculture, University of Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 4).

Chair of Preventive Medicine at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 7).

Lecturer (with qualifications in pure mathematics or in mathematical statistics) in Mathematics—The Registrar and Secretary, The University, 38 North Bailey, Durham (April 8).

Chair of Mathematics at Royal Holloway College—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 8).

Lecturer (with a registrable medical qualification) in Physiology—The Registrar, Trinity College, Dublin 2, Republic of Ireland (April 8).

Second Chair of Mathematics at Royal Holloway College—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 8).

Senior Lecturer/Lecturer in Anatomy; a Senior Lecturer in Physiology; Chair of Pharmaceutics; and a Chair of Pharmaceutical Chemistry at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 15).

Lecturer or Assistant Lecturer (Probationary) (man or woman graduate) in Statistics in the Departments of Mathematics and Psychology—The Secretary, Bedford College, Regent's Park, London, N.W.1 (April 16).

Lecturer in the Department of Physiology—The Secretary, The University, Edinburgh (April 17).

CHAIR OF EDUCATION—The Secretary, The University, Aberdeen (April 24).

READER IN NUMERICAL ANALYSIS AND MACHINE COMPUTATION at Queen Mary College—The Academic Registrar, The University of London, Senate House, London, W.C.1 (April 24).

CHAIR OF NUCLEAR PHYSICS at the University of Cape Town—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and the Registrar, University of Cape Town, Private Bag, Rondebosch, South Africa (April 29).

LECTURER (with research or industrial experience in automatic control and/or engineering systems design) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Registrar, Queen Mary College, Mile End Road, London, E.1 (April 30).

POSTDOCTORAL FELLOW (Organic Chemist), to participate in a study on the biosynthesis of natural products—The Registrar, University College of Swansea, Singleton Park, Swansea (May 1).

CHAIR OF EDUCATION at Monash University, Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia (Australia and London, May 13).

A.E.I. RESEARCH STUDENT (graduate) IN THE PHYSICS DEPARTMENT to carry out research in either experimental or theoretical physics—Prof. R. W. Ditchburn, F.R.S., J. J. Thompson Physical Laboratory, The University, Whiteknights Park, Reading (May 20).

ASSISTANT PROFESSOR IN ANATOMY, with teaching duties in gross anatomy—The Chairman, Department of Anatomy, University of Saskatchewan, Saskatoon, Sask., Canada.

BIOCHEMIST (Senior grade) IN CHARGE OF THE GROUP BIOCHEMISTRY LABORATORY—Hospital Secretary, Altrincham General Hospital, Altrincham.

LIBRARIAN (with previous experience of working in a scientific library)—The Director, Research Station, Fruit and Vegetable Canning and Quick Freezing Research Association, Chipping Campden, Glos.

MASTER TO TEACH BIOLOGY throughout the School to University Scholarship standard—The Headmaster, The Perse School, Hills Road, Cambridge.

MASTER TO TEACH MATHEMATICS with emphasis on sixth form work—The Head Master, Cheltenham Grammar School, Cheltenham.

RESEARCH ASSISTANT (graduate, Graduate Member of the Royal Institute of Chemistry, or with equivalent qualifications) IN ORGANIC CHEMISTRY, to work under the supervision of Dr. G. Shaw on some aspects of the chemistry of nucleic acids and their derivatives—The Registrar, Dept. J/23, Bradford Institute of Technology, Bradford 7.

RESEARCH FELLOW, to work on catalytic reactions in molecular sieves—Prof. R. M. Barrer, Chemistry Department, Imperial College of Science and Technology, London, S.W.7.

SCIENTIFIC INFORMATION OFFICER (Abstractor) (with a degree in agriculture or natural science, and able to translate from German and/or Russian)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire.

VICE-PRINCIPAL—The Principal, Brunel College of Advanced Technology, Woodlands Avenue, Acton, London, W.3.

APPOINTMENTS VACANT

UNIVERSITY OF GLASGOW

LECTURESHIPS IN MECHANICAL ENGINEERING

Applications are invited for Lectureships in Mechanical Engineering, tenable from October 1, 1963, or such earlier date as may be agreed. Salary scale· £1,150 to £1,950 per annum (under review). Initial salary above the minimum for those with suitable professional qualifications and experience. F.S.S.U. and family allowance benefits. The development of courses in the new engineering curricula and well-equipped laboratories provide excellent scope for teaching and research. Teaching requirements exist in the fields of applied thermodynamics and of applied mechanics, including particularly manufacturing processes. Subjects of current research interest include· applied thermodynamics; control systems; fluid power control; heat transfer; mechanical and electrochemical machining; principles of machine design; properties and strength of materials and structures.

Applications (three copies), should be lodged, not later than April 22, 1963, with the undersigned, from whom particulars may be obtained.

ROBT. T. HUTCHESON,
Secretary of University Court.

SCHIZOPHRENIA RESEARCH FELLOWSHIP

The Schizophrenia Research Fund, which has recently been formed, proposes to establish a long-term Fellowship, to be known as the Rothschild Fellowship; tenable for five to seven years, for research into schizophrenia. The grant will be made in the form of a Fellowship either to the individual who is to be wholly engaged on the work or to the head of a department who wishes to include such a post in his department and to associate himself with the work. The holder of the post should have research experience but need not be medically qualified. In certain circumstances the conditions of the Fellowship might be alterable. The salary will be in the range of £2,000 to £2,500 depending on qualifications and experience. Superannuation provision will be similar to the F S.S.U. scheme.

Applications should give details of the projected research and of the qualifications and experience of the proposed holder of the post and the names of three referees; and, unless coming from the head of a department, should state where the applicant proposes to do the work, what facilities and co-operation would be required from the institution concerned and whether these have yet been assured.

Applications should be sent to The Secretary, The Schizophrenia Research Fund, City Gate House, Finsbury Square, London, E C.2, to arrive not later than July 1, 1963.

Research Scientists

UNILEVER PLANTATIONS GROUP have vacancies in their Research Organization in West Africa for the following graduate staff:

1. A PLANT GENETICIST, basic salary £2,000–£2,400 per annum. This is a new and senior appointment suitable for a botanist with a good Honours degree and postgraduate experience of plant genetics. The successful applicant will be required to conduct research into the genetics of the oil palm with particular reference to improving productivity and disease resistance. Later the programme of work may be extended to include other tropical cultures elsewhere in Africa or in the Far East.
2. A PATHOLOGIST, basic salary £1,600–£2,000 per annum. The successful applicant will initially carry out research on diseases of the oil palm but his responsibilities will later be extended to include work on rubber.
3. AN AGRONOMIST, basic salary £1,600–£2,000 per annum. Candidates should preferably have had experience with either oil palms or rubber and must be capable of taking full charge of a comprehensive programme of field experiments.

These appointments will be based in either Nigeria or the West Cameroons. In both territories there is an expatriation allowance which is currently 25 per cent of basic salary, and there are children's education allowances. Terms of service include free passages for the member of staff and also, where applicable, for his wife and children. There is an initial kit allowance. Furnished accommodation is provided. Medical attention while in Africa is free. Tours of ten to twelve months are followed by home leave on full salary for one-fifth of the period of overseas service. There is a contributory Pension Fund.

Applications, giving details of age, qualifications and experience, will be dealt with in the strictest confidence and should be addressed to:

THE AGRICULTURAL RESEARCH ADVISER,
PLANTATIONS GROUP, UNILEVER LIMITED,
UNILEVER HOUSE, BLACKFRIARS, LONDON, E C.4.

UNIVERSITY OF BRITISH COLUMBIA

DEPARTMENT OF ZOOLOGY

VANCOUVER 8, B.C., CANADA

Applications are being sought for a post as Physiologist effective September 1, 1963 The appointment will be made at the Assistant Professor rank (salary $7,000 to $8,400 per annum, plus superannuation, insurance and fully comprehensive medical benefits). Teaching duties will include a course in elementary vertebrate physiology at the undergraduate level. The pursuit of an active programme of research and graduate student training are also essential. Persons will be considered irrespective of the field (vertebrate or invertebrate) but candidates with interests in nerve, muscle, cellular and general physiology will be particularly welcome. Curriculum vitae, publication list, a brief outline of current activities and a list of three referees should be submitted before April 30, 1963. References will only be sought in the cases of applicants who are short-listed for the appointment

Applications should be addressed to: The Chairman, Department of Zoology, University of British Columbia, Vancouver 8, B.C., Canada.

COMMONWEALTH BUREAU OF PASTURES and Field Crops, Hurley, Berkshire, requires Scientific Information Officer (abstractor) with degree in agriculture, or natural science, and able to translate from German and/or Russian. Salary in scale £768 to £1,947. Superannuation. Age, qualifications and experience considered when fixing starting salary.—For further details and application form apply to Director.

QUEEN'S UNIVERSITY

KINGSTON, ONTARIO, CANADA

EXPERIMENTAL PHYSICIST

Applications are invited for an appointment in Experimental Physics from September 1, 1963. Fields of Research in which candidates will be considered are Radio Astronomy, Nuclear Physics, and Solid State Physics. Salary and rank will depend upon qualifications and experience. The minima of the salary scales are as follows: Professor, $12,000; Associate Professor, $9,000; Assistant Professor, $7,000 per annum. The new three-million-dollar physics building with a research wing is on schedule for completion in 1963. One purpose of the appointment is to strengthen postgraduate work. This is an excellent opportunity for a research physicist with a good publication record to find satisfaction in the combination of teaching and research.

Applications and inquiries should be addressed to the Head of the Department of Physics.

UNIVERSITY OF SASKATCHEWAN

DEPARTMENT OF ANATOMY

Applications are invited for the position of assistant professor in anatomy with teaching duties in gross anatomy. Salary range $7,000 to $9,000 according to experience. Excellent research facilities (electron microscopy, tissue culture, experimental medicine). Financial assistance with transportation. Position open as of July 1, 1963, or shortly thereafter.

Apply to chairman of the Department of Anatomy, Saskatoon, Sask., Canada.

BAIRD & TATLOCK (LONDON) LIMITED, CHADWELL HEATH, ESSEX, ENGLAND.
Branches in London, Manchester and Glasgow.

TAS/DO.11

CUTROCK

DIAMOND WHEEL TUBE AND ROD CUT-OFF MACHINE

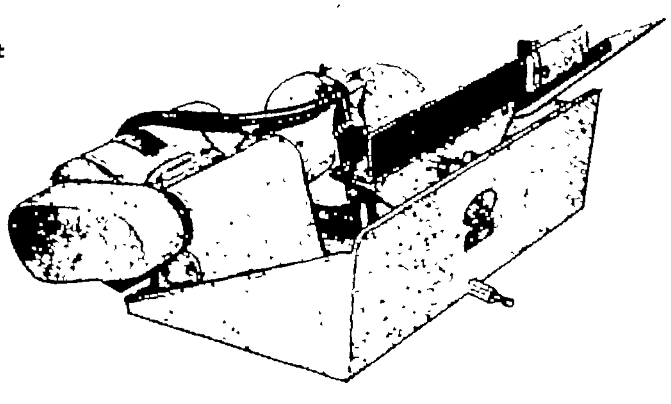
Cuts Glass, Refractories, Ceramics and Semiconductors

CAPACITY

With Large Angle Rest
Tubes from 2″ dia. to 4″ dia.

With Small Angle Rest
Tubes from 0-2″ dia.
Rods from 0-1¼″ dia.

Angle Rests Interchangeable
Mounting bench or stand
Finish grey waterproof stove enamel
Drive flat endless belt
Adjustable stop on angle rest for repetition cutting



Model TCO.104

SPINDLE
High speed vibration free taper roller bearings
Grease lubrication

MOTOR
Totally enclosed fan Cooled continuous rating

COOLANT
Main water or soluble oil
Soluble oil pump and tank unit a separate extra

DIAMOND WHEEL
Standard wheel 6″ dia. × 1 mm.
4″ dia. × .015″ can be fitted for small Rods and Tubes

CUTROCK ENGINEERING CO. LTD.

Phone Finchley 5978-9 35 BALLARDS LANE, LONDON, N.3

SCIENCE AND TECHNOLOGY FOR THE BENEFIT OF THE LESS-DEVELOPED AREAS

MR. J. K. GALBRAITH'S little book, *Economic Development in Perspective*[*], is the outcome of five lectures which the United States Ambassador to India delivered in the summer and autumn of 1961 in five major Indian educational communities. It is not accordingly, as the title might suggest, a commentary on the economic situation of this country and the measures being adopted to meet that situation. It is rather a penetrating discussion of the root problems with which the recent United Nations conference on the "Application of Science and Technology for the Benefit of the Less-Developed Areas", held in Geneva during February 4–20, was concerned. Some at least of Mr. Galbraith's conclusions, too, are remarkably in line with those reached at the most recent Pugwash Conference. They are outlined with wit as well as cogency, and it is encouraging to find that they were reflected in some of the utterances at the Geneva conference.

Mr. Galbraith begins by insisting that the problem of economic development must be considered and handled as a whole, and he even challenges the rigid differentiation of countries into developed and under-developed. We have often failed to inquire whether measures which can contribute to economic development are, in fact, being utilized in a situation favourable to development. Furthermore, capital and technical knowledge may not be the only missing elements. In many of the newer African States and in parts of Latin America the first task is to build competent organs of public administration. Good development plans cannot be created or executed without good government and neither technical assistance nor trained technicians achieve much, or are even much needed, where administration is indifferent or bad.

If the best agricultural scientist can make little headway as adviser to a non-existent ministry, there are circumstances in which popular education must have priority over the dams, factories and other equipment of capital development and in which attention must be focused on the shortcomings of the social order. The most eloquent agricultural extension expert will not convince the peasant of the advantage of growing two blades of grass where one flourished before if the peasant knows full well that both will go inevitably to his landlord. The best-considered forms of agricultural investment or the most sophisticated techniques of agricultural expansion may be worthless unless the cultivator has some assurance that some at least of the gains will accrue to him. Effective government, education and social justice are critically important, and in many countries it is lack of them that is the barrier to advance: until that barrier is removed little will come from capital investment and technical assistance.

Next, Mr. Galbraith challenges the common assumption that, since capital and technically trained manpower are the limiting factors in India and Pakistan, they are the limiting factors everywhere. We can no longer have, he maintains, one diagnosis of the causes of under-development. Rather, we must have the particular diagnosis which fits the particular country. We cannot even assume that if competent planning is possible in India and Pakistan it is possible everywhere. It would, indeed, be a serious mistake to imagine that such planning is essential for nations in all stages of development. In earlier stages it may be neither necessary nor possible.

This point is further elaborated in the second chapter, in which Mr. Galbraith even more explicitly deprecates rigid distinction between the developed and the under-developed countries. He urges that provision of aid is itself a co-operative process in which all countries have something to contribute, and that discrimination is vital in the use of technology if scarce resources are not to be wasted and development itself handicapped. Again, in his third lecture, discussing the theory of development planning, he points out that a good plan must provide a strategy for economic advance: it must not be allowed to become a list of desirable projects. Taking account of both the visible and the invisible dimensions of industrial achievement, its proposals must have regard to a theory of consumption which takes due account of the needs of the particular consumption for the benefit of which in the last analysis the plan is designed. Abundant and efficiently produced food, clothing and shelter are requirements that come before the introduction of the last techniques, and fundamentally Mr. Galbraith is here doing no more than insist on the old but often disregarded adage that the tool should be appropriate to the job.

In his fourth chapter, Mr. Galbraith deals more specifically with education, pointing out that education is of high importance, both as an object of immediate consumption and as a form of investment for future consumption. Neither aspect can safely be disregarded, and Mr. Galbraith does not hesitate to point out some of the implications when education is viewed as an investment or the dangers which attend some experiments with democratic direction in Latin American universities. A developing country must consider its educational system as purposefully as any other form of capital outlay and in the light of the peculiar requirements of development. It cannot simply adapt from the older models, for adaptation is as demanding in its own way as innovation.

Some of Mr. Galbraith's comments in this chapter are particularly interesting in the light of the concern that has been recently expressed over the working of the Commonwealth Scholarships Scheme, especially in respect of the return of scholars to their own country on the expiration of their scholarships. If this aspect appears to have received comparatively little attention at the Geneva conference, many of his other points were well taken. Prof. P. M. S. Blackett, for example, once again stressed the vital importance of considering what known and available technology had to offer to meet the specific needs of a particular country and what research might be required in relation to local conditions. While there might be some new technologies particularly well designed to meet certain specific needs, generally speaking it was the older technologies that were most likely to prove appropriate. It might, for example, be wiser to eschew recent advances for the time being and concentrate on earlier technology of wider potentialities. In agriculture, for example, while many things are useful, mechanization is not the big thing. Water, fertilizers and improved seed can revolutionize agriculture, but to ignore the assistance and potentialities of abundant labour at low cost will only impede development and increase unemployment.

---

[*] *Economic Development in Perspective*. By John Kenneth Galbraith. Pp. vi+76. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1962.) 10s. 6d. net.

This was equally recognized in a discussion on mechanization in the Middle East, South-East Asia and Africa which was concerned particularly with the appropriate type of tractor that was needed. It was suggested that a tractor much more like those in use on English and American farms forty years ago and much less complicated than the modern tractor designed to save labour was really required and should be specially designed with the labour situation in mind. All this, of course, is not new, and is in line with what Prof. Blackett and others, notably at the Cardiff meeting of the British Association, have long emphasized. It is encouraging, however, to find these ideas gaining acceptance at such a representative conference, even if the developed countries were present about four times more numerously than the under-developed countries.

In his final chapter, Mr. Galbraith dealt with a rather more specialized topic—the use of the corporation or company as an instrument of production. Once again he delineates the conditions of success with a clarity that makes his conclusions as relevant to productivity in an advanced as to an under-developed country. A corporation, he points out, is only effective if it has liberty to pursue specified goals. In making decisions every day its autonomy must be nearly absolute, including the right to make mistakes, and must include, subject to safeguards against abuse, the freedom to engage and dismiss its staff. The concomitant of freedom from intrusion on its decisions from outside is, however, that the goals expected of the corporation must be clearly and explicitly defined by society, and while tolerant of errors within the framework of success, society should be wholly intolerant of failure to achieve the specified goals.

In this widely different context, Mr. Galbraith thus gives a definition of public accountability which is highly relevant to any fresh consideration of the nationalized industries or the efficiency of the public corporation. By and large, however, accountability by result could be described as the dominant principle of the book, and it is a principle that found ample expression in the debates at the Geneva conference. It could equally be traced in a contribution from the Natural Sciences Department of the United Nations Educational, Scientific and Cultural Organization on the role of science in the development of natural resources, and in one by R. Dumont on accelerating African agricultural development, both of which recently appeared in *Impact* (12, No. 4; 1962). The latter, moreover, like Mr. Galbraith, stresses particularly the critical importance of an appropriate educational policy.

It is far too early to judge what will come out of the proceedings of a conference at which a hundred countries were represented and some 1,800 papers presented at a cost of some two million dollars, nor was the conference permitted under its terms of reference to pass resolutions for specific action. Nevertheless, it is not to be regarded simply as an exercise in communications, and, if it attested further the place and value of such schemes as the American Peace Corps and Britain's Voluntary Service Overseas in providing help at the sub-expert level, there was some very practical discussion as to how scientific and technical help could be given more effectively while Governments themselves are dealing with the larger strategy of development. The president of the conference, Prof. M. S. Thacker, in his opening address suggested the organization of a world committee, or "brains trust" as he called it, with a continually changing membership, representing various scientific disciplines, as well as nationalities, to evaluate international development plans and assist in their preparation. The director of the Food and Agriculture Organization, Mr. B. R. Sen, suggested a travelling team of scientists who would visit developing areas and keep the international committee in touch with those in the field.

Something of this idea may be seen in the mission to the Indus appointed in 1961 by Dr. J. B. Wiesner, President Kennedy's special assistant for science and technology. The aim of this mission was to study the problem of waterlogging and salinity in West Pakistan, but, as Dr. R. Revelle's paper shows, it found itself drawn into an interdisciplinary analysis and formulation of a development plan calling for unprecedented effort not only in underground water development and drainage but also in fertilizer plants, pest control facilities, education and research establishments and training programmes for technicians, administrators and field workers. There could, in fact, scarcely have been a more impressive demonstration of what is involved if science and technology are to render really effective assistance to the developing countries without waste of precious and scarce resources of trained manpower, capital and equipment.

Perhaps even more important than the demonstration of the immense possibilities was the contribution of the conference to the wide public understanding of the conditions of success and of what is required of Governments and peoples, including the scientist and technologist. The conference itself indicated some of the requirements for fresh thinking about the character and scope of research and teaching if use is to be made of the limited resources of able scientists and technologists to the best advantage. This is as important—perhaps even more important—for such a country as Britain as for less-developed countries, and the conference indicated how large are some of the special opportunities open. There are, moreover, some major problems in organization and administration, both in relation to the use of interdisciplinary teams and in regard to co-operation between existing organizations and institutions which call for forethought and careful analysis. There are priorities in research and development which may have to be re-appraised. However, whether or not new institutions are required, neither Mr. Galbraith in his book nor the Geneva conference leaves any doubt as to the immense amount of goodwill, of knowledge, and of technical and administrative experience already available to serve the developing nations—given the understanding and determination to use it resolutely.

CLOTTING OF BLOOD

Prothrombin

By Prof. Walter H. Seegers. Pp. xxvi + 728. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1962. Published for the Commonwealth Fund.) 120s.

THIS is a remarkable book, and one should not be misled into supposing that it deals only with 'prothrombin' as defined by the majority of coagulation workers. The author's views bring almost the whole field of research on blood clotting within this term. On the factual side he presents the results of many years' work at the Wayne State University, Detroit. Here he has formed an active school of research deeply impressed with the stamp of his personality and ideas. Its numerous publications have been rather widely scattered, and because of their divergence from what has seemed to be the main stream of research they have not always received adequate appraisal in reviews or text-books. It is of the greatest value, therefore, to the student of the history and practice of clotting research to have this authoritative survey.

The first four chapters deal with the definition, purification and properties of prothrombin. The great contribution here is first the separation and definition of a protein in terms of molecular weight, shape and other physical properties, and amino-acid composition, and secondly, the demonstration that it can undergo a series of changes, apparently spontaneously, including the appearance of thrombin activity. This activity is shown by the specific enzymatic action on fibrinogen, and esterase action on synthetic substrates such as TAME. The transformation of these prothrombin preparations can take place under various conditions but most strikingly in the presence of 25 per cent sodium citrate without addition of any other organic substance. This is the key observation, and proves beyond reasonable doubt that molecules with thrombin activity can be wholly derived from the protein molecules defined as prothrombin.

The following seven chapters deal with the activation of prothrombin in the presence of biological factors. It is here that divergencies from generally accepted views become apparent. Prothrombin activation in shed blood occurs in a few minutes following contact with a foreign surface, and in a few seconds in the presence of tissue 'thromboplastins', whereas citrate activation takes many hours. What is the explanation of this rapid conversion? The usual view is that a number of 'factors' interact in sequence to produce a specific prothrombin activator. These reactions are thought to be probably enzymatic, the product of each enzyme-substrate reaction being itself an enzyme which activates the next stage. While Prof. Seegers recognizes the existence of these factors, he seems to consider that they function simultaneously, as non-specific accelerators of the inherent tendency for prothrombin to form thrombin, and to deny their necessary part in sequential reactions preceding this change. He states that "in my perspective the whole order of development is concerned with prothrombin. It is ready to activate. It is 'encouraged' (procoagulants) and 'discouraged' (anticoagulants) by hundreds of substances and millions of combinations of them. My view advocates the existence of factors by the dozens". It is probable that the concept of multiple sequential reactions is a gross over-simplification, and too rigid a picture of events leading up to prothrombin activation; but Dr. Seegers draws a veil over any explanation of the essential function of these factors, including the disastrous effect of their deficiency in the hæmorrhagic states, and the beneficial effect of replacing them.

Prof. Seegers's views on the nature of prothrombin itself are stimulating. He considers that the molecule can undergo a series of transformations, yielding not only thrombin but also other derivatives with different activities in the clotting mechanism. These active derivatives he has named autoprothrombin I, II and *C*, and they probably correspond to factors VII, IX and X of the *International Nomenclature*. Prof. Seegers is wary of synonyms, however, and prefers to use the term "associated word symbol". Terminological wrangles apart, the idea of a multi-potent protein molecule capable of giving rise to different enzymes or activities at different stages of its degradation is intriguing, and might explain the fact that prothrombin and factors VII, IX and X have curious similarities, including their physical properties and their dependence on vitamin K for normal synthesis in the body.

The remaining chapters deal with the inactivation of thrombin, the preparation and properties of fibrinogen and thrombin and their interaction, with clot retraction, anticoagulants, and the hæmorrhagic states, and there is a brief excursion into the immuno-chemistry of prothrombin and thrombin. These contain a mass of useful observations and speculations, lucidly presented.

In general, the book is very well produced, and the style is clear and readable. The author has an enviable knowledge of the classical literature of his subject, and gives many obscure, but valuable, historical references. If he has less respect for much contemporary work he is at least tolerant of views which conflict with his own. In fact, the whole book is coloured by his philosophical attitude to scientific research as an individual experience. Whereas most workers either ignore, or attempt to avoid, subjectivity in experimental work, Prof. Seegers recognizes, and even appears to welcome, it, considering that it should be put to good use in forming a picture of Nature which may lead to new experience, no matter how individual this picture may be. Perhaps one of his quotations (from John Burroughs) aptly expresses this: "The eye is informed and sharpened by the thought. My boy sees ducks on the river where and when I cannot, because at certain seasons he thinks ducks and dreams ducks".

R. G. MACFARLANE

THE CLOUDS

Clouds, Rain and Rainmaking

By Prof. B. J. Mason. Pp. vii + 145 + 20 plates. (Cambridge: At the University Press, 1962). 22*s*. 6*d*. net; 4.50 dollars.

EXPERIMENTAL cloud physics is a new subject: it sprang from the work of Schaefer and Langmuir, carried out in the late 1940's, on the artificial modification of clouds. Their very first results were so impressive as to suggest that control of weather was almost within reach, and a prize so dazzling naturally attracted a great many workers. Many of them, unfortunately, were in too great a hurry, and either designed experiments badly or published results which had little statistical significance. Moreover, professional rainmakers were soon in business, presenting highly coloured advertising material in the guise of research.

Prof. Mason's earlier book *The Physics of Clouds* was the first comprehensive account of the new subject, and much of it was of necessity taken up by a thorough discussion of the heterogeneous mass of experimental data which had accumulated in the previous ten years. Now, by omitting all this detailed criticism, and by some simplification of the treatment, he has produced an up-to-date account of the same subject in about a third of the space.

The author has not changed the arrangement of his material greatly. There is a brief preliminary chapter dealing with the forms and visual appearance of clouds: it would perhaps have been better, in a book which aims to "enhance the enjoyment of those who watch the sky", if the treatment could have been a little fuller. The next four chapters are the heart of the book, and deal in masterly fashion with the processes of condensation and the growth of raindrops, snowflakes and hailstones. The last two chapters are concerned with rain-making experiments and the electrification of thunderclouds.

Most chapters have a kind of appendix in which experiments that the student may carry out for himself are described—an interesting innovation in a book of this sort, though the equipment required is sometimes rather elaborate for the sixth-form or undergraduate amateur of meteorology for whom the book seems to be intended. There are no references to original papers, and only one or two to text-books.

Mathematical proofs are kept few and short, and, as already hinted, historical experiments are not treated in great detail. As a rule all that is given is a short description in general terms, just enough to give the reader an idea of the observational basis of the subject: though a few important and recent experiments are a little more fully treated. Freed from such digressions, the story develops in a natural and logical fashion, and makes remarkably easy reading. The style is good, plain scientific English, which aims only at clarity and conciseness and relies on the subject-matter for its interest. Not even the chapter on rainmaking tempts the author to a lighter treatment, although few episodes in the history of science can be so rich in absurdity and chicanery.

The book is well illustrated with 29 very clear line drawings and 20 photographic plates. The latter include a short but well-chosen "cloud atlas" illustrating nine important cloud types, Prof. Mason's own remarkable photographs of artificially grown snow crystals, and some photographs of early cloud seeding trials which have not since been equalled for dramatic effect. This is a beautiful collection and adds greatly to the interest of the book.

There is a very adequate index for a book of its size. Printing and binding are excellent, in the usual style of the Cambridge University Press, and no misprints were noticed.

B. C. V. ODDIE

STATISTICS FOR STUDENTS OF THE NATURAL AND SOCIAL SCIENCES

Introduction to Probability and Statistics

By Henry L. Alder and Edward B. Roessler. (Series of Undergraduate Books in Mathematics.) Pp. xii + 289. (San Francisco and London: W. H. Freeman and Company, 1962.) 32*s*.

THIS is the second edition of a text-book first published in 1960. The main change is the addition of two chapters, on the *F* distribution and analysis of variance. The book is written to meet the needs of students in the natural and social sciences for a short course in probability and statistics at an elementary mathematical level; only arithmetic and simple algebra are required. The topics covered are standard and unenterprising, namely: the organization and analysis of data; elementary probability; standard probability distributions (binomial, normal); sampling theory including *t*, chi-square and *F* distributions; regression and correlation; analysis of variance; index numbers; time series. A brief and unsatisfactory discussion of multiple-range tests, the one slight deviation from orthodoxy in contents, is given without much confidence in Chapter 17.

The subject of statistics is taught, nowadays, to students with such varied qualifications and needs that there is scope for text-books dealing with the same principles and techniques from different angles and levels of sophistication. The re-issue of the book reviewed indicates that it has been popular. It is clearly and carefully written with well-presented tables and diagrams and also excellently printed and produced. Nevertheless, I think the method of exposition is wrongly conceived.

The development of the theory is formal by means of definitions and elementary algebraic proofs. Inevitably however, because of the restriction on the mathematics, the definitions have to be partial and many important results accepted without proof. Thus sampling is everywhere taken to be from a finite population and the expectation of a variable is treated only for the number of occurrences of an event in *n* trials; this leaves a gap in the logic of the relation between sampling and probability distributions which seems unnecessary. After all, ideas as abstract as those of geometry are taught at school. Minor algebraic results are derived for the probability-levels of *F* although the validity of this distribution for analysing particular aspects of the variability of data is stated but not discussed. Many practical examples are given with the arithmetic worked through in detail but they are nearly always very artificial. Either they deal with such subjects as coin tossing, balls in boxes, seating at table, etc., or, where framed in terms of observations made for a scientific purpose, the results have been constructed only as a numerical counterpart of the theory.

I do not think a natural or social scientist would obtain much of value from the algebraic proofs in this book. He could find from the text how to make estimates and apply tests of statistical significance given measurements suitable for such procedures. There would be little guidance on how he should determine what methods were useful and valid for analysing the data from a scientific investigation. He would spend his time more fruitfully studying a text which attempted to link an intuitive presentation of the principles of statistical theory with empirical studies of actual observations, using much arithmetic. There are a number of books of this kind in the tradition of Sir A. Bradford Hill's classic *Principles of Medical Statistics*. Only thus can the student hope to obtain some insight into the uses of the elegant mathematical methods in the interpretation of crude, unaccommodating, untidy observations.

W. BRASS

MICROBIOLOGICAL STANDARDIZATION

Proceedings of the 7th, International Congress for Microbiological Standardization

London, August 28 to September 1, 1961. Edited by A. F. B. Standfast, D. G. Evans, and B. G. F. Weitz. (International Association of Microbiological Societies: Permanent Section for Microbiological Standardization.) Pp. vii + 556. (Edinburgh and London: E. and S. Livingstone, Ltd., 1962.) 130*s*. net.

THE bulk of this heavy 'paper-back' comprises some seventy papers grouped into fourteen sections under such headings as "Adventitious Agents in Vaccines Prepared from Living Tissues" and "Helminth Vaccines". The sections include from three papers under "The Application of Biological Standards and Reference Preparations in International and National Requirements for Biological Products" to eight under "BCG Vaccine" and "Staphylococcal Antigens and Antibodies". Fifteen of the papers are in French (without English summaries) Several are less than two pages in length and, in view of recent criticisms about 'over-production of scientific literature', some papers could well have been contracted or even omitted altogether, especially when "the details of these experiments have been published previously" as one contributor admits.

As a reference volume the task of locating a specific paper should be easy. In fact, there is no subject-index, and the page headings give only the contributor's name opposite an abbreviation of the section heading. Nowhere are the titles of the papers listed and the "Contents" could most profitably have been expanded to include these under their appropriate section headings. The short "Reports of Sessions" at the end are a partial remedy.

The papers emanate from fourteen different countries (including U.S.S.R., Yugoslavia, Hungary and Czechoslovakia) enabling a comparison of standardization procedures in different countries to be made. This is a truly international volume, but rather expensive.

L. B. QUESNEL

UNIVERSITIES AND THE COMMUNITY IN SOUTH AFRICA*

By Dr. T. E. W. SCHUMANN

Deputy Chairman of the South African Atomic Energy Board

It is of course the duty of a university to keep pace to the best of its ability with the needs of the community it serves. I should say that the University of South Africa is fulfilling this mission in a very special sense. For, amidst the constantly changing conditions of the modern world, it is striving to create facilities for advanced education which the ordinary residential universities of our country are scarcely able to provide. Whether a university which uses postal courses as its main medium of instruction can in all respects be styled an ideal academic institution is of course a moot point. But that is not relevant here. No one can deny that the University of South Africa meets a very real need, and my impression is that it accomplishes its task very efficiently. I know of at least one very gratifying example—that of a student who came from Canada, first to Durban and then to Pretoria, for the specific purpose of completing his degree in mathematics under the professor of his choice.

The University can be felicitated on having on its staff men of such calibre that they are able to draw persons from overseas for academic training. I quote this case, because for those of us who, as members of an older generation, were virtually compelled to proceed to other countries for our advanced education, it is particularly gratifying to observe that in recent years there have been tangible signs that this process is no longer completely one-sided. I am convinced that in the future this University and other South African universities will attract students from beyond our borders in ever-increasing numbers. I have said that a university must always keep pace with the specific needs of the community it serves, but we find that in this technological twentieth century, changes and revolutions are occurring at such a bewildering tempo that adaptation to constantly changing conditions, also by our universities, has become a stupendous task.

No one will deny that we are to-day living in a crucial period in the history of mankind. Last year, I delivered a series of six radio talks entitled "Five Revolutions of the Twentieth Century" on the confused world in which we are living. The central theme of these talks, which included not only the technological revolution but also views on the revolutions caused by the advent of nuclear weapons, of Communism, and of the spiritual capitulation of the White man, was that within the space of a single lifetime we have experienced no fewer than five revolutions, any one of which would have been sufficient to disturb the spiritual equilibrium of any normal person. Every thinking person the world over is therefore faced with the task of a constant reconciliation with new ideas and new conditions. Without a doubt, for South Africa, with her great diversity of races, the task of adaptation in these tempestuous times is infinitely more difficult; and our universities must display a greater measure of flexibility to keep in step with constantly changing needs and fresh challenges.

In her struggle to maintain a measure of equilibrium and stability in these troublous times, South Africa is constantly subjected to bitter criticism, and our universities, too, come in for more than their fair share. Every inhabitant of our country who takes an intelligent interest in present-day developments knows, for example, that the present chaos in large parts of the African continent is by no means, as some optimistic but naïve overseas politicians would have us believe, very nearly a thing of the past, but merely the first stirrings of the turbulent times that lie ahead, and that far greater chaos will yet prevail before conditions change for the better. Knowing full well the shape of things to come, we shall strain every nerve to escape the chaotic developments in other African territories. This is in itself no easy task; and it is greatly exacerbated by constant interference from outside. With more than half of Europe divested of every semblance of democratic freedom, our friends overseas might do well to allow their sudden missionary ardour for suppressed nations to cool down somewhere outside Africa, and to adopt as the war-cry for their modern crusade a slogan such as the 'Liberation of Europe'. Or if this sounds too revolutionary, perhaps they could at least be pragmatic like a prominent British industrialist with vested commercial interests here which he is thinking of expanding, who stated in Pretoria recently: "I deplore your apartheid policy but I would not invest a cent in this country if you did not have it".

But to return to the subject of the development of our universities: a very strange attitude was recently manifested by the most widely read British scientific journal—that unique . . . journal *Nature*, which is to be found in every university library and in hosts of other libraries the world over. Within the space of two months this widely read periodical carried two very scathing leading articles on the universities and learned societies in the Republic. These are articles which call for comment.

The leading article of October 20, 1962 [1], concerns a speech delivered the previous April by a well-known British scientist, Sir Eric Ashby, at the University of the Witwatersrand. His principal theme was the condemnation of separate universities for Bantu in South Africa. I shall presently express a few opinions on this subject. Prof. C. H. Rautenbach, rector of the University of Pretoria, has already replied to Sir Eric. Prof. Rautenbach said, *inter alia*, that what Sir Eric had said in his eloquent peroration on the need for the Africanization of university institutions in Africa lay at the very root of our policy of separation. Experienced British officials from the Colonial period in Africa and elsewhere had already learnt what Sir Eric is now proclaiming, a long time back . . . but this was the first time that he had heard from the lips of an eminent British academician eloquent concurrence with that trend of thought.

It was progressing.

Already there was an implied recognition that there may be as many types of universities as there were communities. . . . Prof. Rautenbach added the rather cutting comment that when, in earlier years, a storm raged over the English Channel, the English newspapers carried banner headlines: "Europe isolated from the World".

The second leading article in *Nature*, of December 29, 1962 [2], discusses "Apartheid in South African Learned Societies". The following quotation will give an indication of the general slant of this article: "Dr. Verwoerd and his colleagues seem determined to leave nothing undone which could engender bitterness and inflame the racialism which is to-day such a grave and growing threat to the future of Africa".

---

* Substance of an address delivered on February 21 at the opening of the academic year of the University of South Africa.

Whether it is mere chance that such conspicuous use should be made of a leading British scientific journal to add its voice to the torrent of preponderantly uninformed attacks on South Africa, and whether one should detect a suggestion of 'inspiration' in this curious coincidence, are matters on which I shall not dilate. I propose however to add a few desultory remarks to Prof. Rautenbach's well-reasoned and very interesting exposition.

First: what psychological explanation underlies *Nature's* touching concern for South African academic institutions when conditions much nearer home should give cause for far graver concern? My experience has been that not so very far from *Nature's* office, behind the Iron Curtain, very little academic freedom remains. At an international scientific conference which I attended some years ago, I was called upon to act as chairman of a small sub-committee which included a Russian and a delegate from one of the satellite countries. On an occasion when we found ourselves alone together, the latter said in rather broken English: "Dr. Schumann, I don't speak at our meetings for reasons which you may guess". To-day, still, at all international gatherings the delegates from the satellite countries, patently and with clumsy efforts at hiding their subordination, subject themselves to the dictates of the Kremlin to an extent that is often painful to behold.

Let us give our imagination free reign and contemplate the well-nigh inconceivable; let us imagine that the University of Moscow were to extend an invitation to Sir Eric Ashby to deliver a public address there: and let us imagine the equally fantastic—that he were to have the courage to advocate in that address the removal of the wire barrier which at present cuts Europe into two from North to South, because of its obvious curtailment not only of academic freedom but also of freedom in the more general sense. Finally, let us imagine that Sir Eric were to return unscathed from such an adventure in Moscow and deliver another address in Johannesburg. Would not his words then carry infinitely more weight, and would we not be far more inclined to give serious thought to his admonitions?

It would perhaps be even more exciting if the University of the Witwatersrand were to succeed in having as its guest speaker at its following triennial 'Chancellor's Address' a scholar from behind the Iron Curtain. If such an erudite guest, say from Prague, which can boast of one of the oldest universities in the world, were to tell us how shamefully we fall short of the lofty ideal of academic freedom as realized in Communist countries, we would accept it without reserve. This suggestion should not be dismissed as a frivolous joke: for, would it really be asking too much of the University of the Witwatersrand seriously to consider extending such an invitation to a scientist of repute from behind the wire barrier? At any rate his visit would be an event of international importance, and it would be difficult to find a hall in Johannesburg large enough to accommodate the audience: and no objection could be raised if after that *Nature* were to write a leading article in support of the Czechoslovakian or Russian pundit's exhortations and admonitions. We would then decidedly be prepared to listen with all due deference and rapt attention, and, if need be, to do penance for our many shortcomings.

Meanwhile the Editor of *Nature* might be prepared to bethink himself on the significant utterances of Sir Eric that universities in Africa should not be mere replicas of European universities, but should adapt themselves to the specific needs of the Negro and the Bantu. I am in favour of co-educational schools, but the fact remains that, like Britain, the Republic has many separate schools for boys and girls, and possibly there are very good educational reasons for this state of affairs. Likewise there may well be many more compelling and convincing proofs that separate educational institutions for different races are preferable to, and give better results than, integrated institutions, and as a scientifically trained person, the editor of *Nature* would surely never reject such a possibility *a priori*. On the other hand, it might be better for his own peace of mind if he were to refrain from delving too deeply into the problem on which he has written with such fluency and ardour. He runs the very real risk of finding himself in the same dilemma as Sir Eric, who, on one hand, advocates the Africanization of the universities of this continent and in the same breath expresses his indignation at the fact that South Africa in all sincerity tries to implement his own recommendation. But then, of course, confused thought-processes often land one in such dilemmas.

One final comment on the triumphant note on which the first article in *Nature* ends: "Sir Eric remarks trenchantly that the only convincing evidence for apartheid existing in a university would be the inferiority of black men to white".

This sentence, obviously intended as a knock-out blow, is so pitifully erroneous as to merit closer analysis. Intellectual superiority or inferiority can never be the primary ground for the need for separate universities. The primary ground was mentioned by Sir Eric himself, who spoke of the necessity for the adaptation of universities to the specific background and way of life of the Bantu and the Negro; in other words, the development and growth of universities on the continent to meet the requirements of the different races. For, after all, one could never suspect Sir Eric of thinking only of the needs of the black races, nor yet of advocating that the whites be swallowed up by the black majority!

But the same sentence contains by implication another erroneous statement, namely, that there is no difference whatsoever in the intellectual potential from race to race. Here is a statement of Communistic origin which is nowadays proclaimed by the liberalists as a sacred dogma throughout the world—and with such success that to-day it demands exceptional courage even to inquire after the scientific proof upon which this doctrine rests. Indeed, everywhere one finds the staggering phenomenon that no one is as intolerant as the liberal when his basic tenet is subjected to analysis. It calls for a high degree of moral discipline to accept the intolerance which has become the most salient feature of our modern liberalist.

Most probably the liberalist thinks that no proof is necessary. Curiously enough, I am not without a hint of sympathy for that attitude, for I must confess that I, too, believe certain things on the strength of personal observation and without any scientific proof. So, for example, I believe that some nations have more musical talent than others. I believe that there is a considerable difference in the intellectual capacity of the Japanese and that of the Pygmies of the Congo, in the intellectual capacity of the Jews and that of the Bushman of the Kalahari, or of the British and of the Australian aborigines. Obviously, however, these beliefs are purely subjective and of no significance to other people, for to-day scientific validation is rightly considered to be indispensable.

Very extensive research on this problem was carried out in the United States of America. During the two World Wars tests were applied to millions of recruits, and always the results were the same—there was a significant difference between the intellectual potential of the American Negro and that of his White compatriot.

Perhaps the Editor of *Nature* could quote research results in refutation of these findings; but I venture to suggest that he will have an exceedingly difficult task.

We find, therefore, that the statements in *Nature* proceed from such poorly grounded premises and such extremely assailable axioms that to discuss its necessarily erroneous conclusions with any logic would be attempting the impossible. If one were merely bent on winning debating issues, one could for example point out that Basutoland, within the boundaries of the Republic but for more than a century under British rule, is very effectively safeguarded against criticism of the type levelled at the Republic. The reason, of course, is that, as a result of the general backwardness of the territory and the high percentage of illiteracy among its inhabitants, there is no university or academic association there.

I shall however not take this any further: my object was merely to lay bare the blind prejudice with which our universities have to contend when even such a prominent and influential journal as *Nature* makes no effort at least to be slightly better informed than the ordinary daily press before launching an attack on our university institutions.

There are so many interesting problems of topical interest that I might have discussed. I might have debated the need in South Africa for what the Germans call a *Technische Hochschule*; I might have spoken of the world-wide demand for outstanding natural scientists and engineers, the results of which are also felt in South Africa. But all I have done is to dwell on an already threadbare theme.

The University of South Africa offers advanced tuition to all racial groups in Southern Africa and even far beyond its borders, and I trust that it will pursue this task peacefully and steadfastly, without excessive complacency, but also without undue concern at the all too capricious so-called 'world-opinion'. I, for my part, am convinced that when in a few years' time the "wind of change" over Africa has spent itself and the world can no longer deny its disastrous aftermath, South Africa will receive due recognition for her efforts at finding a peaceful *modus vivendi* in a country where different racial groups are destined to work out their own salvation: and I hope that when that time comes, it will not be necessary for me to bore you with an address on the eternally recurrent subject of race relations.

" SCIENCE AND APARTHEID " *

[By Dr. R. HOFFENBERG

Department of General Medicine, University of Cape Town]

To the Editor, The Argus.

SIR,—Dr. T. E. W. Schumann's outburst (*The Argus*, February 22) against the highly esteemed scientific journal *Nature* for publishing criticism of apartheid in learned South African societies is reminiscent of Germany in the 1930's, when Nazi 'scientists' strove to defend their racialistic principles against the censure of the civilized world. [Readers who are interested in this point may wish to read the article entitled: "The Pragmatic and the Dogmatic Spirit in Physics", by Prof. J. Stark, published in *Nature* of April 30, 1938.—Editor, *Nature*.]

Speaking as a scientist, I must admit that factual evidence for the equality of all men may be lacking—this happens to be a field in which precise measurements cannot easily be made.

Dr. Schumann knows this, too, which makes his disturbing statements about the racial inequality so much more irresponsible. [The subject of intelligence tests of Negroes and Whites was forcefully challenged by D. R. Hughes, of the Duckworth Laboratory of Physical Anthropology, University of Cambridge, in *The Times* (London) of February 26.—Editor, *Nature*.]

Conflict between prejudice and scientific fact is all too common and discipline is indeed necessary to resolve this dichotomy.

When an unorthodox or isolated view is held, however, the onus is on the holder to prove his point; he must not ask, as Dr. Schumann does, that the rest of the world should prove that it is in step.

Remember Lysenko

I am astounded at the 'double-think' which allows Dr. Schumann to claim that his bigoted attitude requires a 'high degree of moral discipline'.

Discipline, certainly, but surely not moral, since it seeks to suppress the free flow of scientific inquiry!

As deputy chairman of a body engaged in sponsoring research, Dr. Schumann should know better.

If he persists in broadcasting his views, he will only bring to the field of scientific endeavour in this country the sort of opprobium that engulfed Russian scientific achievement after the biased Lysenko papers. (Readers will recall this Soviet agronomist's disastrous efforts to inject Communist doctrine into methods of wheat-production.)

Separate Bodies

I, personally, would like to congratulate the Editor of *Nature* on his two editorials.

The academic world should be kept aware of governmental inroads into education in this country.

The separation of scientific and professional organizations on a racial basis alone, to which the Editor of *Nature* objects, cannot easily be condoned on moral or any other grounds.

To quote this journal (December 29, 1962) it can only 'endanger further the advance of science and learning and the conditions in which they flourish'.

In conclusion I would like to assure the Editor of *Nature* that there is still in this country a substantial body of academicians who deplore this apartheid policy as strongly as he does.

R. HOFFENBERG, M.D., M.R.C.P.

Kenilworth.

With reference to the article in *Nature* on "Apartheid in South African Learned Societies", the Secretary-General of the Commission for Technical Co-operation in Africa: Scientific Council for Africa (Lagos, Nigeria), writes to the Editor of *Nature*: ". . . at the 17th Session of the Commission for Technical Co-operation in Africa, held in Abidjan in February 1962, South Africa was expelled from the Commission because its political policies were most unacceptable to African Member Governments. . . . This latest move on the part of the South African Government to introduce the practice of apartheid into the realm of science is greatly to be deplored by all who are concerned with science itself and

* From *The Cape Argus* (Cape Town) of February 2: reproduced by kind permission of the Editor and of Dr. Hoffenberg.

its application to the needs of newly emergent independent nations".

In an article describing his recent tour of Africa and reporting on his first-hand examination of the practical results of apartheid in South Africa, Mr. Frank Giles, the *Sunday Times* (London) foreign editor, has written (*Sunday Times*, March 9):

"In Johannesburg I talked with many politically-minded Africans, some of them the leaders or representatives of the banned African parties—the African National Congress and the Pan-African Congress—some of them prosperous lawyers, doctors or business men. Taken as a whole, they represented an average of intelligence and capacity far higher than can be met with in most of the newly-independent African States in the rest of the continent, a fact due principally to the higher education of many Africans in South Africa's excellent and hitherto multi-racial universities.

"From now on, however, the African will have to go to the newly-established 'tribal colleges' for Bantu only, where the educational effort is concentrated on what the Government conceives to be suitable subjects for Bantu study. None of the Africans I met had anything but the profoundest scorn for these 'bush universities', designed, so they maintained, to ensure that the African never rises above a certain level: 'We are not interested in a return to tribalisation but in advances that Western civilisation can bring'."

On March 8, the chancellor of the University of Natal, Dr. Denis Shepstone, unveiled a plaque erected by the students at the main buildings of the University in Durban. The plaque is intended to commemorate the death of academic freedom through the imposition of racial segregation in South African universities. It bears the inscription: "The right of this university to determine who shall be admitted as students was taken away in May 1959, and restored . . .". Dr. Shepstone, in his speech, referred to the curtailment by legislation of the autonomy and academic freedoms of South African universities. In thus prohibiting non-White students the Government had curtailed one of the basic freedoms of university autonomy, namely: "Who may be taught". He also appealed for "dedication to the idea of open universities". The ceremony was attended by members of the University Council, the Senate, Convocation, the teaching staff and many students.

NEW PHYSICS BUILDING AT QUEEN MARY COLLEGE, UNIVERSITY OF LONDON

By Prof. G. O. JONES

Professor of Physics and Head of Department

On January 23, the new building for the Department of Physics at Queen Mary College was formally opened by Sir Harrie Massey, in the presence of nearly 200 senior members of universities, Government and industrial offices and laboratories, local schools and other organizations. Deputizing at short notice for Sir Nevill Mott, who was prevented by illness from attending, Sir Harrie—describing himself as the "wrong half of Mott and Massey"—gave a racy exposition of some of the realities of modern university physics. The great virtues of practising science in university departments were that teaching and research were then united, that there was continuous rejuvenation by the flow of young people through the university and that one's choice of research was free. But the enormous growth and change in physics since the War posed serious difficulties for modern departments. The growth of physics made satisfactory teaching in three or four years an increasing problem, since physics was a basic professional training, called for by technologies of all kinds. The changes in the techniques of physical research and the increase in team-work added problems which demanded that the University physicist should have adequate financial, technical and administrative support.

Reasonable amenities were essential for the large staffs who would work in modern departments of physics, and the design of buildings could contribute greatly. In declaring the new building open, Sir Harrie expressed the opinion that it was both workmanlike and attractive and would provide opportunities for "fun at a high cultural level".

The new building (Fig. 1) is designed for an annual student intake in the special honours course of 60. There will be 40–50 full-time postgraduate research students working for the Ph.D. degree, an academic staff of about 20, 6–10 postdoctoral research Fellows or research assistants and about 40 technical, secretarial and other staff. The building was erected in two stages. The first stage, a large eight-storey block, consisting mainly of teaching laboratories and lecture rooms, was completed in 1960. The final stage, a three-storey wing consisting mainly of research rooms, was completed in 1962.

In order to reduce traffic through the building, the main lecture theatre has been placed where it can be entered directly from the entrance hall. It seats about 140 in a steeply raked terrace and is furnished in beech and mahogany with upholstered tip-up seats. An unusual feature is a set of double-glazed wooden louvres covering most of one side of the theatre. To the audience looking towards the lecturer only the woodwork can be seen. Walkers in the corridor outside can, however, look directly into the theatre, and the lecturer can look outside. Two very large revolving chalk-boards are power-operated and cleaned. There are full facilities for showing slides and films from a projectionist's console and service points for demonstration experiments.

A preparation room for lecture demonstrations is adjacent to the main lecture theatre. It connects also with two smaller lecture rooms, seating about 60 and 80 respectively, one directly, and the other by service lift.

The five upper floors of the building house the teaching laboratories, nearly the whole of one floor normally being allocated to the needs of a given group of students. The laboratories have their own preparation rooms, optics rooms, photographic dark rooms, seminar rooms and small libraries for private study, but are very different from each other in detail. The third-year laboratory has also a large students' workshop and glass-blowing room, and a computing room.

The main research area of the building is concentrated in the first floor. There is, however, a vertical column of staff rooms at one corner of the building, designed primarily for convenience in supervising teaching laboratories. and many of these are combined with research laboratories so that there is, in fact, research in progress on every floor above the ground-floor.

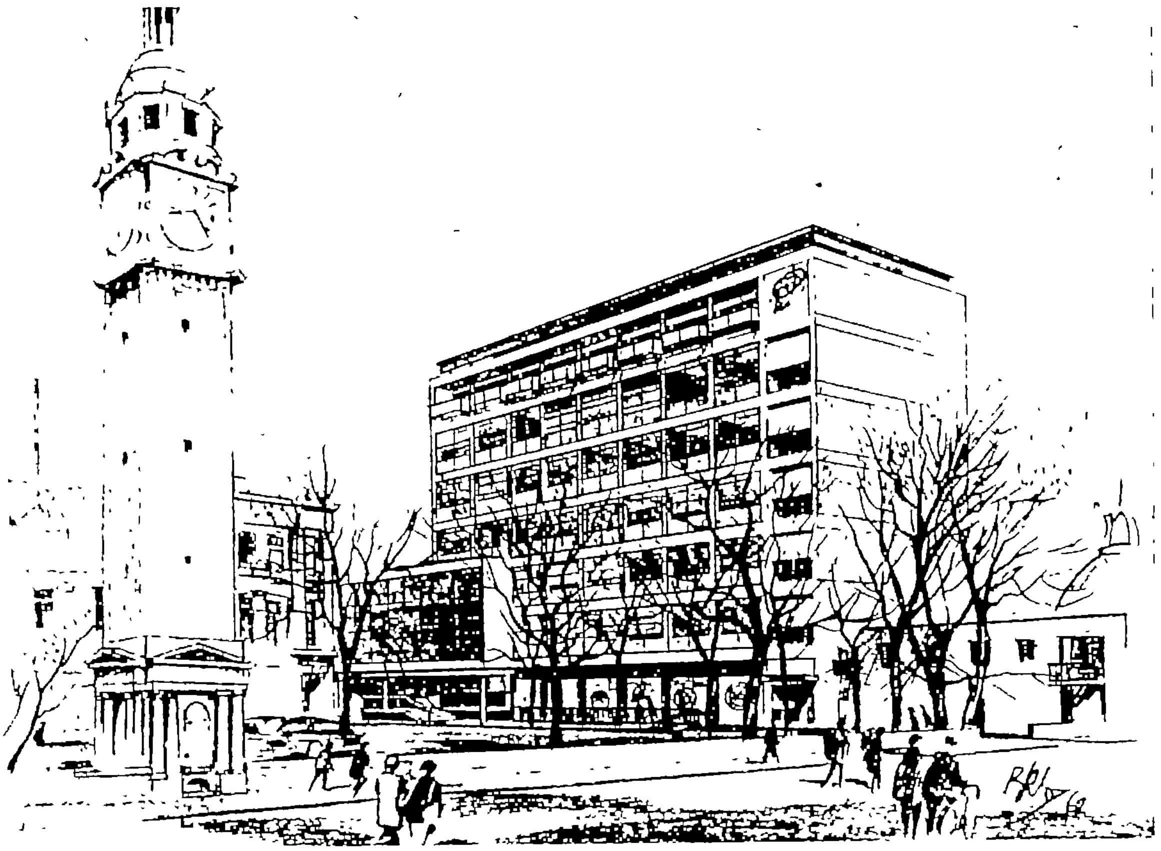

Fig. 1 Architects' sketch of the new physics building, Queen Mary College (University of London) (Architects Playne and Lacey and Partners)

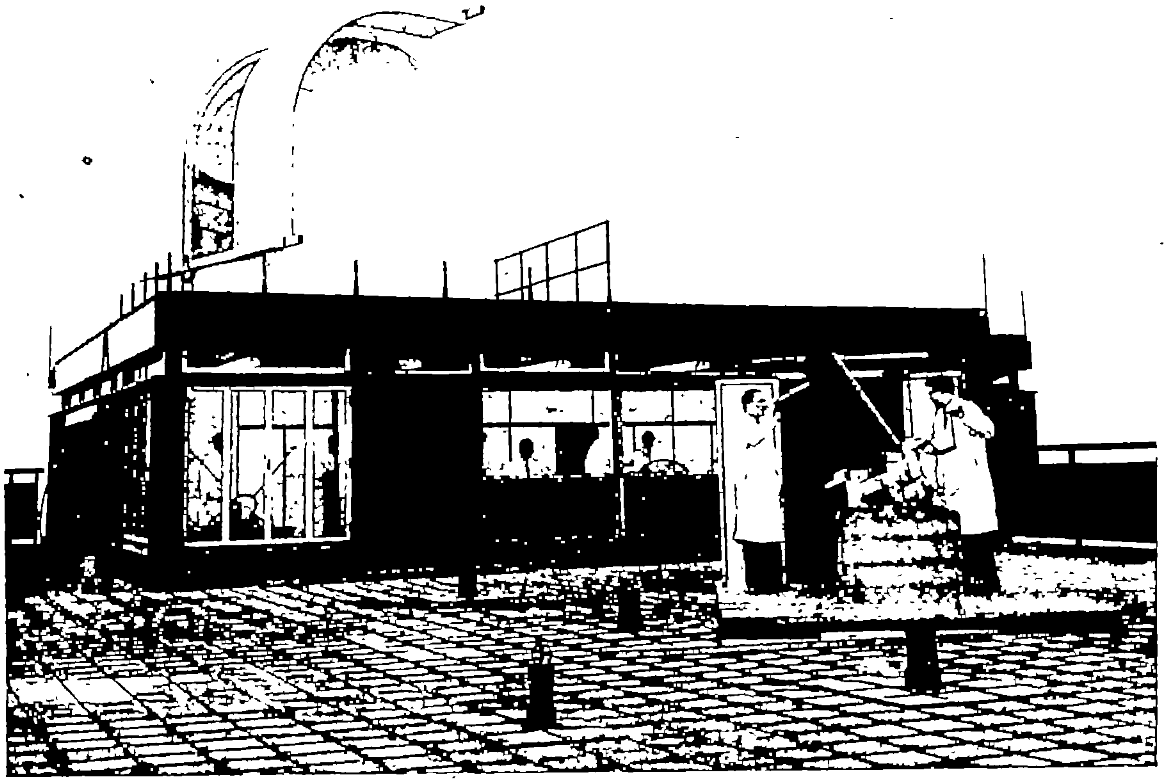

Fig. 2. The astrophysics laboratory on the roof of the physics building (by courtesy of *The Times*)

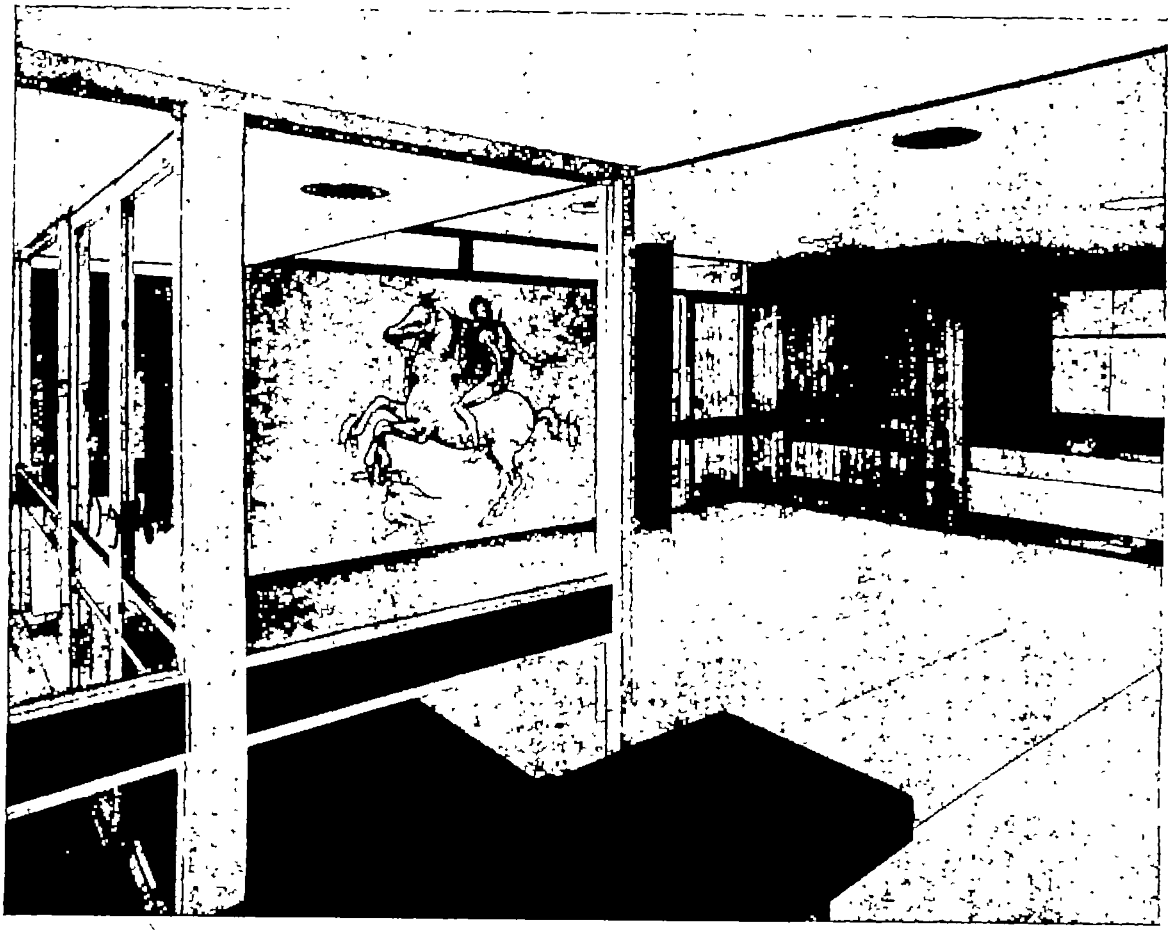

Fig. 3. A view of the entrance hall, showing a photographic enlargement of a Leonardo drawing

The research rooms have been made of many shapes and sizes in order to provide flexibility. There is at present a wide range of research carried on in the Department, the main studies being in low-temperature physics, sub-millimetre spectroscopy, nuclear magnetic resonance, high-energy nuclear physics, astrophysics at sub-millimetre wave-lengths, architectural acoustics and in other branches of solid-state physics, including the study of ferroelectrics and X-ray crystallography. Many of the theoretical studies in progress are related to the experimental programme. Students working in theoretical physics have a suite of small rooms, each accommodating two workers, near the main experimental research area.

There are a departmental library open to third-year undergraduate students and research workers, and a room for research seminars.

The main departmental offices are adjacent to the head of department's room and near those of senior members of the department, and the laboratory steward has a room and clerk's office adjacent to the main entrance hall.

The main service rooms are centrally situated, near the main research area of the building. They include a large main store, a suite of dark-rooms and rooms for specimen preparation, instrument repair, drawing, computing and a first-aid room. There are a large main workshop with an office for the technician-in-charge and subsidiary workshops for research students and for brazing. There are a large room for compressors and liquefiers which houses two Philips air liquefiers and an A. D. Little helium liquefier, and an office for the technician-in-charge. At semi-basement level there is a further set of service rooms which include two radioactive laboratories and a chemical laboratory.

Rooms and laboratories throughout the building share the same general design features. Throughout the building the built-in furniture is either of beech and sapele, or of beech and afromosia, matching the movable furniture in use. Wherever experiments are to be done, there are aluminium slotted strips and strips of soft wood attached to the wall at several fixed heights. Window walls are kept quite clear of services so that desks and tables may be used at the windows. Walls opposite windows, leading into the corridors, are provided with as many built-in cupboards as can be fitted.

Piped services are brought to service shelves which project from the walls at bench height. Among the unusual piped services are return lines for helium gas, waste lines for gases to be discharged at the top of the building, and lines for special high-pressure and low-pressure gas supplies (such as hydrogen and oxygen) and for high-pressure water.

To avoid flooding, all laboratories have drains at floor-level. A feature of many research rooms is that the doors, like those of railway train compartments, have large glass windows which can be lowered.

Electrical supplies are brought to service panels immediately above the service shelves. A feature of these supplies is that a very large number of 240-V a.c. points are supplied for 13-amp fused plugs, and relatively few points for other supplies, which include 240-V d.c., 12-V a.c., 1 kc/s a.c., 415-V 3-phase a.c., and spare lines. Considerable care has been taken to avoid electrical interference. All the steelwork of the frame of the building was carefully bonded during construction. Filters are provided on all the electrical supply systems—particularly at joints—in order to reduce pick-up from outside and to prevent interference generated within the building from

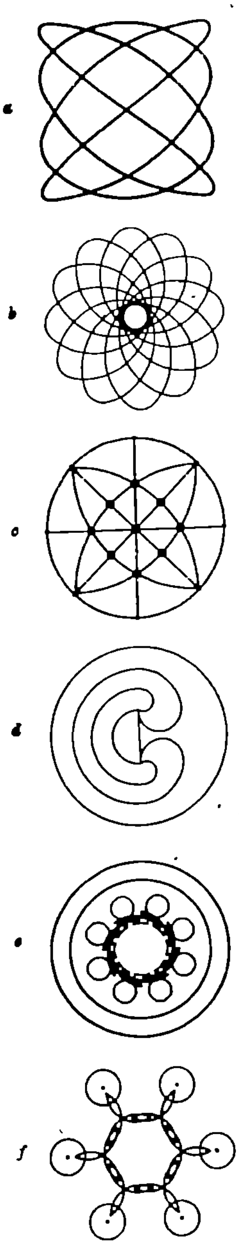

Fig. 4. Designs used for the tile patterns
a, a Lissajous figure; *b*, path of a particle in a precessing orbit; *c*, the stereographic projection of a cubic close-packed structure; *d*, spreading of dislocations from a Frank–Read source; *e*, a cavity magnetron; *f*, the electron-orbital scheme of benzene

being distributed. Special care has been taken to shield the supply cables. A limited access special earth is provided in selected laboratories quite separate from the ordinary a.c. earth. No commutator motors or other devices producing sparks are allowed in the building. All heavy electric motors and devices requiring large currents (such as workshop machinery) are supplied separately direct from the sub-station. The laboratory a.c. outlets are fed via a voltage stabilizer. Some laboratories have tungsten lighting, although fluorescent lighting is generally used.

One room extending over two floors is designed for high-voltage apparatus and completely screened, with a shuttered opening leading to an adjacent research room at the upper level.

On the roof of the building there is a laboratory (Fig. 2) designed for astrophysical experiments at millimetre wave-lengths. The roof of this laboratory carries a revolving dome housing a 60-in. reflecting telescope.

Where there is heavy vibration, as in the main workshop and in the liquefier and compressor room, the whole floor is mounted separately from the rest of the building. Two first-floor rooms have especially strengthened floors for heavy equipment, and one, in which a *Varian* 3-ton magnet is installed, has a removable wall and window so that heavy equipment may be hoisted directly into position from outside the building.

A feature of nearly all rooms is that the pipes and cables are brought in behind panels or above the false ceilings and cannot be seen. Moreover, alterations and additions to services can be made without defacing the building. The delivery area for the building is a yard with entrance at lorry tail-board height to the goods lift which serves all floors. Gas cylinders are stored in the yard with underground connexions to the main distribution points inside the building. There is also an underground store here for acids and solvents. All the air supplied to the building is cleaned by filtering.

A great deal of thought has been devoted to the problem of making the building comfortable and pleasant as well as efficient. Among the decorative features are a photographic reproduction of a drawing by Leonardo da Vinci in the entrance hall (Fig. 3), a mural painting by Feliks Topolski in the research wing, a sculpture by Mr. T. B. Huxley Jones on the exterior of the building, and a series of tile patterns decorating the lower part of the exterior, based on physical ideas derived from several branches of physics (Fig. 4).

Technicians working in the department have their own common room and locker rooms with showers. A pleasant amenity is the departmental museum, situated in the middle of the research area on the first floor, which is used as a meeting place and tea-room for all permanent occupants of the building. The museum houses a scientific exhibition and is also used as an art gallery, open to the public and advertised in the artistic press as Gallery 273. The changing exhibitions in this Gallery provide an interesting background for those who work in the building.

CARCINOGENESIS AND CANCER PREVENTION

By Dr. P. R. J. BURCH

Medical Research Council, Environmental Radiation Research Unit, Department of Medical Physics, University of Leeds, General Infirmary, Leeds 1

THE most important application of theories of carcinogenesis is to the problems of cancer prevention and therapy. It is generally believed[1] that a viral ætiology should open up the possibility of prophylaxis through immunization. By contrast it is thought[2] that somatic mutation hypotheses are 'pessimistic' because, to quote Burnet[3]: " . . . Everything suggests that, somatic cells being what they are, the impact of the environment must inexorably lead to an accumulation of mutant cells, some of which will have malignant descendants if life persists long enough".

Unfortunately, evidence analysed in previous articles[4,5] makes it reasonably certain that most human malignancies have a genetic basis. It is highly probable that somatic mutation (of genes or chromosomes) is a causal factor in all human cancers, while inherited mutant genes or chromosomes certainly feature in the ætiologies of many[4]. Although oncogenic viruses may often play a causal part in malignant development in the young (through 'horizontal' transmission) their involvement in adult malignancies is probably rather rare.

One very important and obvious implication follows from the conclusion[4,6] that many cancers are 'prezygotic'[6]—involving one, and very occasionally two, inherited mutant genes, or an inherited mutant chromosome[7]. If carriers of inherited 'carcinogenic mutations' could be identified before the reproductive age is attained, and if they could then be dissuaded from procreation, a great reduction would result in the incidence of prezygotic malignancies in succeeding generations. It is estimated[4] that the majority of malignancies are of this kind, and hence the importance of developing tests to identify carriers can scarcely be over-stressed. Although the detection of carriers of the Ch^1 chromosome[7] is a relatively simple matter, the task of diagnosing 'point'-type gene mutations is likely to prove much more difficult. Nevertheless, a solution to this scientific problem may be confidently anticipated; the public acceptance of eugenic practices is more problematical, but even in this domain, the widespread apprehension concerning cancer could overcome entrenched attitudes.

Eugenic practices would, however, have no effect on the incidence of postzygotic tumours—those devoid of an inherited "carcinogenic mutation". This article is concerned with: (1) the roles of gene mutation, viruses, hormones and immune reactions in malignant transformation; (2) the theoretical possibility of limiting the incidence of postzygotic cancer.

Mechanisms of Carcinogenesis

A broad outline of the proposed overall mechanism of human carcinogenesis is given in Table 1; it resembles earlier proposals[4,8].

Table 1. POSSIBLE GENERAL OUTLINE OF THE STAGES OF HUMAN CARCINOGENESIS

INITIATION[a,b] (MULTI-STAGE) ↓	Random accumulation of mutant nuclear genes, or occasionally gross chromosomal defects in a generative somatic cell (ref. 4). In many malignancies, especially in the young, one, and occasionally two, mutations will be inherited (refs. 4, 5).
CARCINOGENIC 'NUCLEOTYPE' ↓	The initiation stage culminates in the emergence of a cell in which particular genes associated with the control of differentiation and mitosis have undergone mutation (or occasionally, deletion). Normally, except in childhood and adolescence, four specific mutations will be present in the carcinogenic 'nucleotype'—a cell the nuclear constitution of which confers malignant potentiality.
CARCINOGENIC CELL ↓	When the cytoplasmic constitution reflects the nuclear changes, the resulting cell is described as the carcinogenic cell. It is still not neoplastic.
LATENT PERIOD[b] ↓	There is usually a long interval—up to many years—before the carcinogenic cell is converted into a malignant cell. This phase probably corresponds to the 'promotion' stage discerned in experimental chemical carcinogenesis. A hypothesis of the latent period is described in this article.
CANCER CELL[c]	

(a) Phase, or stage, principally affected by ionizing radiations.
(b) Oncogenic viruses may affect either or both of these phases.
(c) Cancer formation is often preceded by a premalignant condition, in which there is a partial loss of control of normal mitosis and differentiation. In this stage, it is probably cells containing three out of the four carcinogenic mutations that exhibit hyperplasia.

The theory of the initiation-stage is based principally on an analysis of age-specific mortality statistics, epidemiological evidence, and inheritance relations for spontaneous human leukæmias. However, the dose-response and age-dependence relations for radiogenic malignancies are quantitatively consistent[4,9,10] with the view that ionizing radiation can induce somatic mutations characteristic of the initiation-stage. A highly critical test of the theory of the initiation-stage is given by the values of the mutagenic efficiency of radiation in somatic cells deduced from several investigations, ranging from the effects of small doses of obstetric X-rays on the fœtus, to those of large doses of nuclear-bomb radiation on the survivors at Hiroshima[4,9,10]. The values found span the same kind of range as that observed for the radiogenic induction of mutations in mouse germ cells[11] (at 7 recessive loci) and in somatic cells[12] (at 4 of the same loci).

An understanding of the overall carcinogenic process requires an interpretation of the phenomenon of the latent period. Among the Hiroshima and Nagasaki survivors, the onset of radiogenic leukæmia between the years 1947–58 followed on approximately Gaussian-type distribution in time with a median latent period of about 6–7 years[9,13,14]. It is significant that the latent period is not noticeably dependent on age; furthermore, the mean latent period for the onset of chronic myeloid leukæmia at Hiroshima was about 6 years, whereas that for acute myeloid leukæmia was about 8 years. This effectively disposes of the view that the variability in time of onset simply reflects differences in the growth rate of malignancies. The facts suggest rather that the growth-phase—from one, or a few cells, to symptoms and signs of leukæmia—is relatively short, and that one or more random events intervene between the formation of the carcinogenic nucleotype and the malignant transformation[8]. Provided these events are not further somatic gene mutations (if they are, they should be inducible at the time of irradiation) then it no longer follows that somatic mutation will necessarily lead to cancer development, for these malignant-transforming processes may be preventable. This possibility will be discussed later.

Initiation Stage

Detailed conclusions regarding the initiating requirements for leukæmias have been described elsewhere[4,9,10]. The key derivation is that in the absence of stress (for example, bacterial infection, viral, or hormonal factors), a malignancy generally develops from a cell with four specific mutations, one of which, in spontaneous carcinogenesis is frequently inherited. Evidence discussed in a preceding article[5] indicates that two of the carcinogenic mutations affect both homologous genes at a particular locus, or possibly, at one of a limited number of loci. In the case of leukæmias and genetically associated cancers, cytogenetic and pedigree evidence imply that

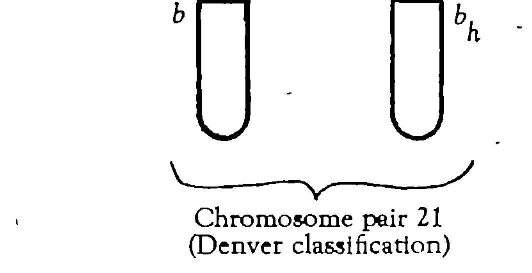

Fig. 1. Proposed approximate location of genes involved in the initiation of leukæmias and genetically associated cancers. The 'a' locus genes are assumed to have a regulator function, and the 'b' locus genes a combined operator–structural function, although the reverse attribution is equally likely

this locus is on chromosome 21; the same kind of observations suggest that a second distinctive locus on chromosome 21 is also implicated. (This 'second locus' could conceivably be one of several alternatives.) It will be assumed that the other two 'carcinogenic mutations' affect both homologous genes at this second locus. Although the symmetry of the situation (Fig. 1) makes this an æsthetically attractive assumption, it will be shown that it is also consistent with the evidence.

Consider now the functional properties of these two loci—are they structural, regulator, or operator[15]? Apparently, recessive inheritance at one locus (arising from a consanguineous marriage, for example) can result in childhood malignancies[8]. It will be shown that this locus is unlikely to have a structural function; on the other hand, the immunological evidence indicates that at least one of the 'carcinogenic loci' is of the structural kind. A fuller insight can be obtained by considering the general characteristics of the latent period and of malignant cells.

Latent Period and Malignant Cells: Some Characteristics

The following phenomena must be accommodated in any adequate theory of the carcinogenic process:

(1) The existence of a long and variable interval between the completion of the initiation-stage (the formation of the 'carcinogenic cell'[4]) and the onset of malignant growth. In experimental carcinogenesis, it appears that this interval can be shortened by co-carcinogens.

(2) The distribution of the latent period, as already mentioned, is approximately Gaussian in form. This phenomenon is also observed in experimental animals[16].

(3) When the malignant transformation occurs, it is generally irreversible. There are, however, hormone- and virus-dependent tumours in experimental animals, and the same may be true of man.

(4) Human malignancies are often, but not always, preceded by a pre-malignant or hyperplastic condition[17].

(5) Some evidence (see later) indicates that the malignant cell has lost immunological specificity.

(6) In contrast to (5), other evidence points to the existence of cancer-specific antigens.

(7) The malignant cell tends to be de-differentiated, and there is a connexion between the acuteness of a leukæmia, for example, and the extent of de-differentiation. Nevertheless, wide variations in tumour cell differentiation are found.

(8) It is now apparent that malignant growth is usually characterized not by an increase in the mitotic-rate of generating cells, but by the fact that differentiation, and loss or death of cells is arrested[18]. Furthermore, both daughter cells emerging from a mitosis must sometimes become generating, or mitotically competent cells. This latter property may represent one of the most important distinctions between benign and malignant neoplasms. In the former, it will be very rare for both daughter cells from a mitosis to become generating cells, and growth of the neoplasm will be either very slow or non-existent. The rate of growth of an established primary cancer, or metastasis, will be determined by the relative frequency of 'doubling-divisions'.

(9) An outstanding property of the cancer cell is a surface change, resulting in lowered adhesion[19].

The following hypothesis represents an attempt to provide a unified interpretation of the foregoing phenomena, and to relate them to the conclusions regarding the initiation-stage.

Hypothesis of Latent Period

It is proposed: (1) that two autosomal loci are generally implicated in carcinogenesis (as illustrated in Fig. 1) and that in carcinogenic and malignant cells in human adults, all genes, a, a_h, b and b_h (homologous at both loci) are generally mutant; (2) one locus, 'a', has a regulator function; (3) the other locus, 'b' has a structural function; (4) for human leukæmias, and genetically associated cancers, these loci are situated on chromosome-pair 21; (5) genetically associated malignancies involve at least one common allele or at least one common locus.

Recent observations[20] suggest that the concepts of Jacob and Monod[15] regarding the regulation of protein synthesis in bacteria may well be applicable (at least in essence) to mammalian cells. However, in the latter, regulator genes do not, apparently[21], control the synthesis of metabolically sequential enzymes as they do in bacteria.

Mutant structural genes will determine the synthesis of 'mutant' protein via 'mutant' messenger RNA (*m*-RNA). A polypeptide of the altered protein will exhibit an anomalous amino-acid sequence (frequently associated with a change in molecular folding) and, in general, this should produce a 'not-self' steric pattern[22]; the anomalous protein should therefore be autoantigenic (that is, capable of reacting immunologically with one or more specific antibodies). In the absence of viral or hormonal factors (see later), it is suggested[4,8], following Green[23], that the malignant transformation of the carcinogenic cell depends on a specific immune reaction between complementary-pattern antibody and the autoantigenic protein. According to Green[23], the autoantigen is probably a lipo-protein, and this attribution is supported by the findings of Vogt[24] and of Björklund[25] *et al.* On this view, the long duration, and the Gaussian distribution of the latent period, will arise from the small (and random) probability of specific antibody reacting with the exceedingly low concentration of 'homologous' autoantigen (borne by only one, or at the most, a few, carcinogenic cells).

It is now necessary to consider how this immune reaction could effect the malignant transformation of the carcinogenic cell. It is suggested that the lipo-protein, a component of the cell membrane and endoplasmic reticulum, is normally the 'source' of one or more factors (cf. inducer and repressor metabolites in bacteria) that combine with or affect repressor molecules to determine the differentiation state of the cell, and its overall metabolic pattern. Dumonde *et al.*[26] have shown that antibody, present only on the surface of mouse ascites tumour cells, and in the absence of complement, can exert profound changes on intracytoplasmic particles and enzyme concentrations. It is axiomatic that "Cancer is clearly the result of a defect of the homeostatic mechanisms which maintain the balance among cells in an organism"[27], and the problem is to relate the immune reaction to an irreversible change in a control system that involves two loci, one of which is structural and the other regulator in function.

It is proposed that the essential change produced by the immune reaction is the removal, inhibition, or alteration of a 'differentiating-factor', *DF*. The altered factor, or condition, will be symbolized by *NDF*—which could well correspond to the absence of *DF*. It is suggested that *NDF*, in conjunction with 'mutant' repressor from the mutant regulator locus 'a', causes the inhibition of *m*-RNA synthesis at the homologous mutant structural genes at locus 'b'. The consequent inhibition of 'control' lipo-protein synthesis and the disorganization of the endoplasmic reticulum now removes the source of *DF*. Hence, an immensely important theoretical requirement—an irreversible change—has been established. Normal differentiation in the affected cell, and its daughters, can no longer proceed, because the source of *DF*, the control lipo-protein, cannot be re-established. The change-over from *DF* to *NDF* will affect *m*-RNA synthesis at many structural loci in addition to 'b' (by inhibition or release), and the balance of enzyme concentrations, and therefore of metabolic pathways in malignant cells will be different from that in normal cells. (This is, of course, a well-known phenomenon.) The anaplastic malignant cell will tend to be geared to mitotic, rather than normal differentiation functions (as in embryonic life), and the disorganization of the endoplasmic reticulum will produce a morphological deterioration.

In bacteria, repression of enzyme synthesis can be very variable—from less than 0·1 per cent to rather more than 10 per cent of the unrepressed value[13,14], and it must be supposed that a rather wide variation of control lipo-protein synthesis can exist in neoplastic mammalian cells. The degree of repression will probably depend on the extent of complementarity between the mutations at the regulator and structural loci. (It is envisaged that the operator locus, which in bacteria is very closely linked to a structural locus[15], actually forms a part of the structural locus, 'b'.) When the 'b' locus is poorly repressed, there may be sufficient lipo-protein synthesis in some cells to yield a concentration of *DF* adequate for more or less normal differentiation. On this view, chronic leukaemias, for example, with a slow growth-rate and little de-differentiation, result from a rather 'leaky' inhibition of the 'b' locus.

This suggested control system is outlined in Fig. 2 where, for simplicity, only one chromosome of a homologous pair is shown.

Although the role of *DF* in cellular differentiation is conjectural, some form of cytoplasmic-nuclear interaction is essential, according to Mather[15], to account for the allied phenomenon of paramutation (Brink)[16]. The present hypothesis has the merit of satisfying the following stringent conditions: (1) 'dormancy' of the carcinogenic cell from the time of its formation to neoplastic conversion; (2) the long latent period (resulting from very low concentrations of autoantigen and specific antibody) and its Gaussian distribution; (3) the irreversibility of the malignant transformation (because of diminished concentration of *DF*); (4) the loss of antigenic specificity in the malignant cell—as a consequence of the absence of a normal lipo-protein; (5) the gain of a cancer-specific antigen (not necessarily the same in all cancers) due to the residual synthesis of an autoantigenic lipo-protein; (6) the variability in the 'acuteness' and degree of differentiation of a cancer—depending on the extent of repression of *m*-RNA synthesis at the 'b' locus, and the concentration of *DF* in the cytoplasm; (7) compatibility with the conclusions regarding the initiation stage; (8) a change in the surface properties of the cancer cell; this should follow from the inhibition of synthesis of a lipo-protein component.

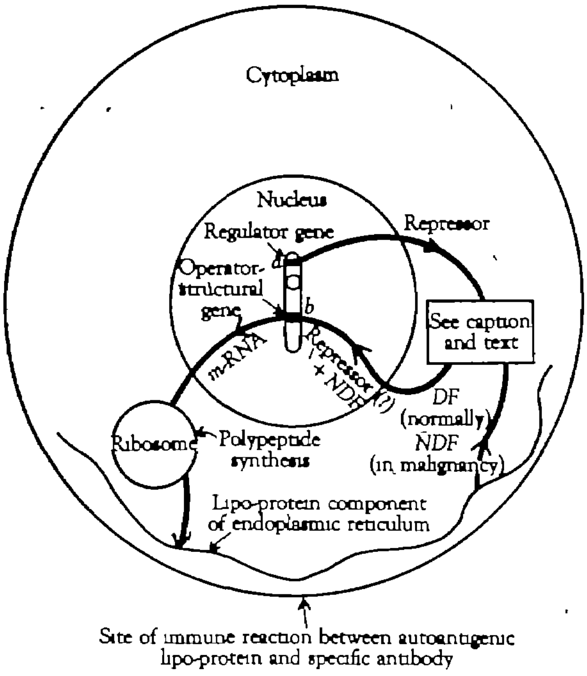

Fig. 2. Proposed metabolic pathways in malignant transformation. For clarity, only one chromosome of the autosome pair 21 is illustrated. The operator–structural gene 'b' determines the amino-acid sequence of a polypeptide in the 'control' lipo-protein, forming a part of the endoplasmic reticulum, and cell membrane. When 'b' is mutant, the lipo-protein is autoantigenic. An immune reaction between autoantigenic lipo-protein and antibody of the appropriate complementary steric specificity affects the nature of differentiation–mitosis metabolites in the cytoplasm. (Other environmental factors such as contact with neighbouring cells, hormones, etc., can also affect these metabolites.) Normally, the presence of *DF*, and repressor molecules from non-mutant regulator loci produce a pattern of inhibition and release of structural loci appropriate to ordinary differentiation. However, when mutations at the 'a' and 'b' loci are complementary, the replacement of *DF* by *NDF* through antibody attack causes the 'mutant' repressor plus *NDF* to inhibit *m*-RNA synthesis at the mutant 'b' locus. The concentration of autoantigenic lipo-protein is now greatly reduced, and the source of *DF* is irreversibly diminished. Normal differentiation is no longer possible even in the absence of antibody, and the pattern of structural locus activity is that of the malignant cell

The common phenomenon of pre-malignant hyperplasia[17] remains to be accounted for. From the analysis of the initiation-stage, it was concluded that this probably involves a proliferative advantage, or hyperplastic growth of cells containing three out of four carcinogenic mutations. This will be accompanied by a changed differentiation. It is suggested that in hyperplastic cells, homologous regulator genes (a and a_h) are mutant, but that only one (heterozygous) structural gene, b or b_h, is mutant. For, if homologous structural genes become mutant when only one or neither of the a, a_h genes is mutant, antibody attack (probably in conjunction with complement) is likely to prove cytotoxic because the cell with a heterozygous mutant regulator gene will be unable to repress the synthesis of autoantigenic lipo-protein. However, with a and a_h mutant, and b or b_h mutant, antibody attachment to lipo-protein, a part of which is autoantigenic, may reduce the concentration of *DF* sufficiently so that occasionally a cell will undergo mitosis instead of normal differentiation. By the same token, a hormone with mitotic-stimulating properties ('stimulation' may entail the neutralization of mitotic-inhibition) could well give rise to a hormone-dependent neoplasm where cells have homozygous mutant regulator genes and a heterozygous mutant structural gene. Removal of the hormone will permit *DF* to re-establish a high degree of normal differentiation, and the hormone-dependent tumour will then regress. The occurrence of the fourth carcinogenic mutation in a cell in a hormone-dependent tumour would, of course, establish autonomous growth, and it is well known that tumours in experimental animals that are initially hormone-dependent often become autonomous. (It is interesting in this context that human growth hormone resembles α- and β-globulins[21].)

Some Implications

Certain implications of the preceding hypothesis may now be considered. Suppose an individual inherits homozygous mutant structural genes (as the result, for example, of a consanguineous marriage). According to the Burnett[22]–Lederberg[23] approach to immunology, and a recent development of it[24], the presence of 'antigen' in the organism since fertilization should result in the development of immune tolerance to that 'antigen', which is indistinguishable from 'normal self'. Consequently, the carrier of homozygous mutant structural genes should develop immune tolerance to the protein the structure of which is determined by them. Such a carrier should, therefore, be no more prone to cancer than ordinary non-carriers. (Only further mutations at that locus will produce autoantigenic lipo-protein.) Nevertheless, in a mating between a homozygous carrier and a non-carrier, every offspring will be heterozygous for the structural gene. Although the 'penetrance' during a life-span of 70 years of a heterozygous 'carcinogenic mutation' (in the phenotypic form of any malignancy) is likely[8] to be in the region of 0·5, very occasionally, even large families should be observed in which neither parent is cancerous (one being a homozygous carrier of mutant structural genes), but where every (heterozygous) offspring develops cancer. A remarkable family, effectively answering to this description, has been mentioned by Lentz[34]. In this family, neither parent developed cancer, although all four sons died of gastric carcinoma, and three out of the four daughters died of carcinoma of the uterus; the remaining, fourth daughter, although not herself a victim of cancer, was very probably a genetic carrier, because her daughter died of carcinoma of the pancreas. Such families, however, will occasionally arise where either or both parents are heterozygous carriers (of either structural or regulator genes), and very extensive studies will be necessary to elucidate completely the genetics of cancer. Obviously, the same allele is involved in various carcinomas, and the importance of detailed and systematic pedigree evidence is immense. If a particular allele at the structural locus is common to many carcinomas, immunological tests should reveal a common lipo-protein antigen in the malignant cells of human carcinomas. Precisely this claim has been made by Björklund *et al.*[35], who found a similar, heat-labile, lipo-protein antigen in each of 60 individually tested human carcinomas. Even more astonishing is the "suggestive evidence" of McKenna and Blakemore[36] for a common antigen, transcending species barriers, in various human and murine (cultured) malignant cells. The antigen is absent from cultures of non-malignant tissue.

Antigenic differences between malignant and normal cells should not be confined to cytoplasmic constituents. It is postulated that the substitution of *NDF* for *DF* in the malignant cell introduces a changed pattern of gene regulation and therefore of *m*-RNA synthesis. There are several indications[36,37] that histones are associated in some way with the suppression of *m*-RNA synthesis at structural loci. Although an RNA repressor molecule complementary to the DNA of the structural gene seems a better candidate for the actual agent of repression, histones could presumably conjugate with the RNA–DNA complex. Whether histones are the cause or the effect of repression, antigenic differences between the deoxyribonucleoproteins of malignant and normal cells may be anticipated. Such differences have indeed been demonstrated by Messineo[38]; antigens found in the deoxyribonucleoprotein fraction from leucocytes of normal cells differ from those found in the cells of leukæmic patients. Byers *et al.*[39] report specific antigens in the nuclear fraction of human carcinomas that were destroyed by DNase and by pepsin (in addition, specific antigens in the microsome fraction of a sarcoma were destroyed by RNase and pepsin).

Numerous reports of circulating antibody in cancer patients may be directly attributable to residual autoantigenic control lipo-protein; but antigens may well be released from necrotic tissue, and it is also conceivable that the chromosomal defects that commonly arise in malignant cells may sometimes be associated with the synthesis of autoantigenic proteins.

Viral Carcinogenesis

Within the context of the present hypothesis, the following potential ætiological roles for oncogenic viruses can be distinguished. The list does not pretend to be exhaustive, and more complex virus–genome interactions can be imagined.

(1) *Virus as co-carcinogen.* A virus of the appropriate antigenic specificity will cause proliferation of particular immunologically competent cell lines. Should the host defence system fail to eliminate or inactivate the virus, a dependent neoplasm could arise. In this ætiology it is envisaged that the viral antigen plays a part equivalent to that performed by antibody in 'normal' carcinogenesis. The induction or latent period should be short. In the new-born immunologically immature mouse, for example, such viruses would be ineffectual; should they persist, acquired immune tolerance to the virus could well develop. However, subsequent mutation of the virus producing an antigenic change could initiate dependent neoplastic growth in an immunologically competent cell line of the appropriate specificity.

Neoplasms induced by this ætiology will tend to be diffuse in origin; the virus could contain RNA or DNA.

(2) Proliferation of a virus in the cytoplasm could affect the synthesis of *DF*. If through competitive or other means the concentration of *DF* were drastically diminished, a dependent neoplasm could be initiated. (A carcinogenic cell would be rapidly transformed into an autonomous malignant neoplasm.) The introduction of this type of virus into the new-born mouse could induce a dependent neoplasm of diffuse origin. The origin in adult mice would also be diffuse. Such a virus should contain RNA.

(3*a*) Proliferation of an RNA virus in the cytoplasm could interfere with the synthesis of control lipo-protein. The consequent diminution in the concentration of *DF* would lead to a dependent neoplasm (or to malignant transformation of a carcinogenic cell). Induction would again be rapid. This type of virus would be carcinogenic in the new-born mouse.

(3*b*) Exactly similar results to those in 3*a* would follow if a virus interfered with the synthesis of *m*-RNA at the control structural locus. Tumours induced by both of these ætiologies should be diffuse in origin.

(4) A DNA virus might transduce or mutate a regulator gene, or affect it by a 'lysogenic-type' action. A neoplasm would result only when the control structural genes are also mutant. This mechanism would be effective in mice of all ages, although it would be characterized by a long latent period. An immune or hormonal attack would be required to convert the carcinogenic into a malignant cell. Except for large doses of virus, the origin of tumours for this and the next mechanism will tend to be uni-focal.

(5) A DNA virus might affect operator–structural control genes by mechanisms similar to those in (4). Neoplastic development would require mutant regulator genes. Again, conversion from the carcinogenic to the malignant cell would require an immune or hormonal attack, and the latent period would be long.

In all the foregoing examples, the outcome of introducing viruses into an organism will depend on the competition between the rate of the carcinogenic process and the rate of elimination of viruses by the defence mechanism of the host. The significant reduction in the yield of thymic lymphomas in the irradiated mouse when a part (other than the thymus) of the animal is shielded[40] could well be due to the preservation of immunologically competent cells from the cytotoxic action of the irradiation, and their subsequent neutralization of the lymphoma-inducing virus.

In general, there is insufficient evidence to decide whether any actual oncogenic virus belongs to any one of the hypothetical types enumerated here, although it is interesting that all of them would appear to have some parallels in known animal oncogenic viruses (see a review by Kaplan[41]). The *in vitro* studies of Dulbecco[42] on the RNA-containing Rous sarcoma virus indicate that this is probably a type 2 or 3*a* virus. Thymectomy in mice greatly reduces the incidence of virus-induced lymphocytic leukæmias and lymphomas. Miller and others[43] have shown that the normal maturation of the thymus in the immediate neonatal period is essential to the development of full immunological competence, and it is possible that thymectomy suppresses a malignant-transforming immune reaction. If this is the case, a type 4 or 5 oncogenic virus may be implicated. Alternatively, thymectomy may simply remove the source of cells that would otherwise become malignant. However, Miller[44] has shown that when thymic tissue from a donor is subcutaneously grafted to a thymectomized mouse, the thymic lymphosarcoma induced by the Gross virus generally consists of host, and not graft cells. This favours the view that thymectomy suppresses a malignant-transforming immune reaction, and this interpretation is further supported by the observation that the effect of a grafted thymus is in part genetically determined.

If, as suggested by the present analysis of the initiation stage, viruses may often play an important part in human childhood malignancies[4], this is probably the consequence of relative immunological immaturity during the early years. The repeated failure to demonstrate virus involvement in non-leukæmic malignancies in adult humans may be due to the genuine absence of such an ætiological factor. The immunological competence of adult man may well be responsible for this, potential oncogenic viruses being neutralized by an adequate concentration of specific antibodies (probably cell-borne). On the Burnet[22]–Lederberg[23] view, the number and variety of specific antibody-producing cells should depend not only on the size of the animal but also on its growth-rate, and the (absolute) time available for the development of immunologically competent cells. Small short-lived animals are at a severe disadvantage in these respects, and it is suggested that this is the principal cause of their vulnerability to oncogenic viruses. Should the present hypothesis of carcinogenesis be applicable to such animals, non-genetic factors (in addition to genetic ones) are essential to account for an appreciable incidence of a malignant condition in them. The probability of a cell in an organ of the mouse acquiring spontaneously even 2 specific somatic-mutations within the normal life-span of the mouse will not be high at normal mutation-rates.

Cancer and Immunization

Attempts to immunize against cancer have been based on two assumptions: (*a*) cancer-specific antigens exist; (*b*) passive immunization with the appropriate antisera, or a suitable reinforcement of the host's immune system by active immunization, will reject the autoantogenic tumour.

Although several authors[25,35,36,45] claim to have detected antigens specific to spontaneous human malignancies (and see reviews by Milgrom, Rapport and Graf[46], and Old *et al.*[47]), others[48] find that tumour cells are deficient in certain proteins, and exhibit a concomitant loss of immunological specificity. The latter type of finding constitutes the basis of the 'deletion theory' of carcinogenesis.

According to the present hypothesis, both schools should be correct, and the cancer cell should be characterized by the simultaneous loss of one specific 'antigen' and the gain of another. In addition, the general balance of enzyme activity will be altered. The acquired autoantigen should normally be present, however, only at a low (but variable) concentration, and accordingly the outlook for orthodox cancer immunization appears to be poor. Experiments with animals give little encouragement. Some success in this direction has been obtained by Levi *et al.*[49], but in their experiments the test system was an Ehrlich ascites tumour inoculated into *C3H* mice. Despite an overall antigenic compatibility between the ascites tumour and the normal inbred *C3H* mice, small antigenic differences could account for the fact that anti-tumour serum obtained from inoculated mice produced some degree of passive immunization. This type of experiment with non-autochthonous tumour inocula is, however, largely irrelevant to the problem of immunization against spontaneous tumours. Comments of a similar nature have been made by Kaliss[50].

Several workers[47,51] have shown that " . . . sarcomas induced in rats and mice by the polycyclic aromatic hydrocarbons are antigenic in the animal, and in the inbred strain of origin[52]". Furthermore, some degree of immunization against this form of chemically induced tumour can often be obtained. On the other hand, and significantly, the immunization procedures used have no detectable effect on the incidence of spontaneous sarcomas[52]. This evidence indicates that these chemical carcinogens affect not only the differentiation–mitosis control system but that they also form, or induce, cellular antigenic constituents that are not associated with the control lipo-protein. These antigens will be absent from spontaneous tumours, and immunization therefore has no effect on the latter.

In an attempt to immunize against spontaneous tumours, Hirsch and Iversen[53] pre-treated inbred or back-cross *C3H* mice (free from the mammary tumour agent) with injections from strain-specific or strain-related mammary tumours of recent spontaneous origin. There was a significant reduction in the age at which spontaneous mammary tumours appeared in the pre-treated mice. If the present view is correct—that spontaneous tumours retain a low concentration of auto-antigenic control lipo-protein, then, pre-treatment should if anything slightly sensitize the host, thus producing a condition that is more likely to enhance, than to diminish, the malignant-transforming immune reaction between antibody and autoantigenic control lipo-protein in the carcinogenic cell.

It can be claimed that theory is in excellent accord with the evidence from cancer immunology.

Does this mean, therefore, that at the outset, attempts at cancer immunization are doomed to failure? The orthodox approach has so far proved unrewarding, but there remains an untried, fundamentally opposite procedure—the induction of acquired immune tolerance, or of immunological paralysis.

Acquired Immune Tolerance, Immunological Paralysis and Cancer Prophylaxis

According to Green[13], and to the present hypothesis, the malignant transformation of the carcinogenic cell frequently depends on an immune reaction between specific antibody (probably cell-borne[22]) and autoantigenic lipo-protein. It follows, therefore, that if this reaction could be prevented, the carcinogenic cell would remain 'dormant' and, viral or hormonal intervention apart, the latent period would be extended indefinitely. In other words, the tumour would never develop. In principle, this condition of non-reactivity could be induced through the phenomena of acquired immune tolerance or immunological paralysis[22,54]. The mechanism of immunological paralysis is obscure, and the practical difficulty of administering—and perhaps maintaining—a high concentration of cancer specific antigens would seem to be formidable. Equally, the induction of acquired immune tolerance may involve insuperable difficulties, and the following procedures would be involved:

(1) Identification and isolation of cancer-specific antigens. The major theoretical difficulty here is that if mutations in the structural control gene are random, a wide range of alleles should result, with the consequent possibility that control lipo-proteins, of slightly different immunological specificities, will be synthesized in the carcinogenic cells of different individuals. Distinctive tissues may be expected to synthesize tissue-specific control proteins, although pedigree and immunological evidence already quoted indicates that closely similar antigens may be common to many types of tumour.

(2) Assuming that the problems of identification and isolation of cancer-specific antigens can be overcome, and that supplies of effective antigens can be made available, then to induce tolerance, their presence will be necessary at an adequate concentration in the immunologically developing organism. In human beings (though perhaps not in mice) this would almost certainly entail the formidable difficulty of introducing the antigens into the embryo or fœtus via the maternal circulation and the placenta. The presence of antigen should prevent the formation of clones of antibody-producing cells, that, in the normal course of events, would react with the autoantigenic control lipo-proteins in the immunologically mature organism[22].

(3) To maintain tolerance, antigens would need to be injected at regular intervals.

The foregoing procedures could be very readily tested in mice, although infection with types 1, 2 or 3 virus, or hormonal transformation of the carcinogenic cell, would defeat their purpose; unfortunately the relevance of such procedures to man would appear to be rather remote. Nevertheless, the carcinogenic- (as opposed to the malignant-) cell with its (theoretically) high concentration of autoantigen, probably represents the stage of carcinogenesis most vulnerable to prophylactic measures. If the induction of acquired immune tolerance or immunological paralysis should prove to be impracticable, some method of blocking the immune attack on the carcinogenic cell (by pseudo-antibody ?) or alternatively, of rendering it cytotoxic, might still be devised. A better understanding of the action of the complement system might assist the latter objective.

The possible therapeutic measure of artificially supplying and maintaining a sufficient concentration of *DF* to every malignant cell in a tumour and its metastases should be considered. However, the hypothetical *DF*, or the '*DF* system', would first need to be identified, and superficially, this form of therapy would appear to offer little promise. Theoretically, prevention would seem to be more practicable than cure.

This article should not be concluded without some reference to the possible biological consequences of cancer elimination. According to the hypothesis[4,5] of the initiation-stage of carcinogenesis, the equilibrium-level of mortality from pre-zygotic tumours is determined by the mutation frequency in germ cells (including certain chromosomal aberrations incurred at meiosis) and the selective mortality rate in genetic carriers before, and during, the reproductive phase. In the absence of any exploitation of eugenic practices, the elimination of cancers in early life would eventually lead to a great increase in the number of carriers of (normally) 'carcinogenic mutations'—unless some additional unforeseen checks should arise. Provided anti-cancer measures were scrupulously maintained, this might be of little concern, but there is a risk that these mutant genes may cause some other, as yet unappreciated, detrimental effects[55]. Although it is not easy to imagine sequelæ as devastating as cancer, it should not be assumed automatically that its elimination would be wholly beneficial. But this perhaps is an anxiety we can bequeath to our doubtless more knowledgeable successors.

A part of this work was performed during a one-year leave of absence at the Oak Ridge National Laboratory, Oak Ridge, Tennessee.

OBITUARIES

Prof. T. S. Wheeler

ALL who had ever met Thomas S. Wheeler, professor of chemistry in University College, Dublin, will have been deeply grieved to hear of his sudden and unexpected death on December 13 within a few hours of having attended a meeting at the College of Pharmacy. His untimely passing at the age of sixty-three is a tragic loss to the University College where he was not only an outstanding scientist and administrator but also a personal friend respected by everyone who, in whatever capacity, worked or studied there.

Although his work for the College over nearly eighteen years must remain unfinished, Prof. Wheeler has by his energy, his passion for progress, and his genius for inspiring others, much more than fulfilled his own modest ambition to leave the department better than he found it. It is much to be regretted that he has not lived to see the completion of the new chemistry department, now under construction, to the planning of which he had devoted much time and thought. His work for chemistry, for scientific education in Ireland and in other fields will long be recalled. Not least will he be missed by the Irish Government, which frequently sought his advice on practical scientific problems, advice which he was uniquely able to give owing to his remarkably wide interests in science, combining as he did extensive knowledge and research interests in all branches of chemistry and even in physics and mathematics. Prof. Wheeler endeared himself to all by his understanding, his humour, and his felicity of phrase.

Prof. Wheeler was born in Dublin in 1899. He was educated at O'Connell Schools and received a scholarship which enabled him in 1916 to proceed to the Royal College of Science for Ireland, where he gained the associateship in chemistry in 1920. He became for one year a demonstrator and research worker at the Royal Technical College in Glasgow, where his work gained him the external Ph.D. degree of the University of London. In 1923 he was appointed a research chemist at Woolwich Arsenal, and during 1928–31 was a senior chemist at the Winnington Research Laboratories of Imperial Chemical Industries, Ltd.

Prof. Wheeler left industry in 1931 to become for seven years principal and professor of organic chemistry at the Royal Institute of Science, Bombay, where he was active in building up flourishing schools of teaching and research and starting a postgraduate Department of Chemical Technology. He returned to Ireland in 1938 as State chemist in charge of the State Laboratories, and was appointed to the chair of chemistry in University College, Dublin, in 1945. Prof. Wheeler was the author, or joint author, of some two hundred original papers, patents, articles, and books, on an extraordinarily wide range of topics, the largest single group being on the organic chemistry of flavonoids and related compounds. Prof. Wheeler gave freely of his time in the service of many important committees and his loss will be keenly felt not only in Ireland and Great Britain but also in India and the United States, where he had many warm personal contacts. He is survived by his wife, whom he married in 1926, a son and two daughters. W. BAKER

Dr. J. S. Greenhow

THE death of Dr. J. S. Greenhow on November 3 at the early age of thirty-four has brought to an untimely end the career of a leading exponent of the study of the upper atmosphere by radar methods. In the span of twelve years he published nearly forty important research papers, and for most of these he was either the sole author or the leader of the research.

A graduate of the University of Manchester, he began his research work at Jodrell Bank in the early years of meteor observations by radar methods. He became interested in the characteristics of the meteoric ionization and the factors controlling the movement, diffusion and decay of the meteor trails. Observation of the motion of meteor trail echoes proved to be the best method for studying winds in these regions of the upper atmosphere. In this way, Dr. Greenhow obtained detailed information of wind speeds and directions, diurnal variations, turbulence and so on. Further knowledge of the conditions in the upper atmosphere came from the rates of decay of meteor echoes, and these were used to derive the atmospheric densities and temperatures. The initial stages of trail formation then attracted his attention, and he also studied how echo properties vary with the radar wave-length.

In 1960, Dr. Greenhow joined the Royal Radar Establishment at Malvern. Here he made the first meteor observations obtained at a wave-length as short as 25 cm. The results strikingly confirmed the view he had expressed previously, that a meteor trail has a surprisingly large initial radius, of the order of a metre. At the short wave-lengths, the trail also generally appears as only a short column of ionization close to the meteor. More recently, he has led the first British experiments to investigate upper atmosphere ionization by the important method, discovered in the United States, of measuring the radio scattering by free electrons at the short wave-lengths which penetrate through the ionosphere. He completed his last paper, "The Electron Scattering Cross Section in Incoherent Backscatter", just before his last brief illness. He had given no hint to his colleagues that for more than a year previously he had known that he might not have long to live.

All Dr. Greenhow's work was characterized by directness of approach, elegance of experimental techniques, and clarity of analysis, so that valuable and interesting results followed from every investigation. He was extremely capable in all stages of a research, from designing and constructing apparatus to the writing of the final report. He had a purposeful and stimulating enthusiasm which made him an inspiring team leader. At the same time, he was modest and friendly, and he is greatly missed by his colleagues. He leaves a widow and a daughter.

J. S. HEY

Mr. Herbert Womersley

HERBERT WOMERSLEY, a distinguished student of the taxonomy of the Acarina and primitive insects, died in Adelaide on October 14, 1962, at the age of seventy-three.

He was born in Warrington, Lancashire, on April 10, 1889, the son of amateur lepidopterist, Fred Womersley. He trained as an industrial chemist in soap and chemical manufacturing, specializing in fuel economy and water softeners. In his youth he became an amateur entomologist with a leaning to microscopy, getting training from Abraham Flatters in Manchester, and publishing an early paper in Flatters' journal, *The Micrologist*, on the use of terpineol. In 1914 he joined the Royal Army Medical Corps, and later transferred to the Chemical Corps, Royal Engineers, in one of the British Gas Companies, seeing service on the Western Front. In 1917 he was transferred back to Great Britain in explosives manufacture. In 1920 he moved from Warrington to Bristol as a departmental manager of Christopher Thomas and

Bros. soapworks. In Bristol he identified himself with local naturalists' groups, serving as president of Bristol Naturalists Society. In his evenings and week-ends he studied the apterygote fauna of the south-west of England. In several years he established himself as an authority on the Collembola and Protura, initially under the guidance of J. M. Brown.

He worked with great industry and speed—habits that never left him—and soon collections of foreign material were sent to him for working up. He was elected as associate (*hon. causa*) to the Linnean Society. In 1930 he was able to transfer to entomology in a professional capacity, as entomologist, Pasture and Field Pests Section, Council for Scientific and Industrial Research (now C.S.I.R.O.), stationed in Western Australia, his work having attracted the notice of Tillyard, then chief of the Division of Economic Entomology. Womersley's task was to study cultural, chemical and biological methods of controlling the lucerne flea (Collembola: *Sminthurus viridis* (L.)) and the red-legged earth mite (*Halotydeus destructor* (Tucker)), which were causing considerable damage. This work was done in collaboration with the Department of Agriculture, Western Australia. In the biological control field it was found that the bdellid mite *Biscirus lapidarius* (Kramer) was an important predator on *Sminthurus*, and the results were considered promising enough for lots of this mite to be transhipped by air to various Australian localities in an effort to establish them locally.

In 1933 Womersley was appointed to the South Australian Museum as entomologist, on the death of Arthur M. Lea. Here he found his most important role, that of a descriptive taxonomist, with a virtually unworked continent before him. Initially he continued his earlier studies on the Apterygota, these culminating in his monograph, *The Primitive Insects of South Australia* (1939), which, in fact, monographed the whole of the Australian fauna.

Afterwards, he gradually changed to the Acarina, and within a few years was virtually pre-occupied by the vast number of new mites requiring classification and description. His *magnum opus* was his monograph of the Trombiculidae of the Oriental and Australian regions (1952), which ran to 673 pages. These scrub-typhus and scrub-itch mites had assumed importance during the Second World War, and immense collections of them were referred to him during the war years and for years afterwards, as teams of workers concentrated on this subject in Malaya, New Guinea, India, China and Japan.

Womersley retired as entomologist in the South Australian Museum in 1954, but was immediately appointed acarologist, a salaried position created for him. The reference collection of mites he built up there is one of the great reference collections of the world. He retired from this position at the age of seventy, in 1959, but continued his work with zest, although by then dogged by increasing ill-health. However, his enthusiasm never waned, and he was working on the mites until a fortnight before his death.

He identified himself with naturalists' organizations both in England and Australia, taking an important part in wild-life conservation. A former president of the Royal Society of South Australia, he was awarded the Verco Medal for his achievements in biology in 1943, and in 1962 was made an Honorary Fellow.

R. V. SOUTHCOTT

NEWS and VIEWS

Biology in the University of East Anglia:
Dr. J. A. Kitching, O.B.E., F.R.S.

DR. J. A. KITCHING, whose appointment to a chair of biology in the University of East Anglia has just been announced, has been reader in zoology at Bristol since 1949, and was first appointed there as lecturer in 1938. From 1939 until 1945 he went first as a Research Fellow to Princeton and, with the outbreak of War, to Canada, where he worked on protective clothing for aircrew and served as secretary to the National Research Council's Committee on Aviation Medicine. A graduate of Trinity College, Cambridge, he is best known for his classical work on the osmoregulatory function of the contractile vacuole in Protozoa; he has also contributed to investigations on ciliary movement and on the physiology of Suctoria, where his interest in the experimental effects of high hydrostatic pressure has played a significant part. He has also made substantial contributions to marine ecology, recently as leader of an annual group of scientists and students investigating the hydrography, fauna and flora of Lough Ine, in south-west Ireland. In Bristol he played a leading part in the establishment of the Joint School of Biological Chemistry under the late Prof. W. E. Garner, and served as the secretary of its first Board of Studies. With Profs. T. A. Bennet-Clark and J. Dainty, the University of East Anglia has thus established an outstanding team to head its new School of Biological Sciences.

Chair of Transport at Imperial College of Science and Technology:
Prof. C. D. Buchanan

AT the outbreak of the Second World War, the part-time Maybury chair of highway engineering lapsed with the retirement of Prof. R. G. Clements. The small post-graduate school started by him has continued studying problems mainly allied to the needs of lesser-developed countries. The increasing national need for traffic engineering and long-term planning in urban and highway developments demands detailed examination and research. The College's new civil engineering building will enable the Department to undertake this work and to direct proper attention to the wider study of the complex social and planning problems of modern transportation. Mr. C. D. Buchanan, at present urban road traffic adviser to the Ministry of Transport, has been appointed to a newly established chair of transport tenable at the College as from October 1. Mr. Buchanan, an old student of the College, has held many distinguished posts in the Ministry of Transport and of Housing and Local Government. The appointment of Mr. Buchanan, who has a recognized professional reputation in this field, with qualifications in town planning and architecture as well as civil engineering, will enable detailed attention to be paid to long-term planning in urban and highway development.

The Institute for Operational Research

THE Operational Research Society and the Tavistock Institute of Human Relations have concluded negotiations for the establishment of an Institute for Operational Research as a non-profit-making body. This new Institute, of which Mr. W. N. Jessop will be the director, will be set up within the framework of the Tavistock Institute. The Operational Research Society is a scientific body which does not itself engage in project work. The Tavistock Institute consists of a linked group of active research units—so far, the range has covered sociology, social psychology and medical psychology, and it will now be extended to include operational research. Each unit has a high degree of autonomy and the new Institute will be free to develop its own programme and associations, both within and outside the Tavistock Institute.

The Operational Research Society is associated with the new Institute through representation on the Tavistock Council and through a special Advisory Panel with Sir Charles Goodeve as chairman. The aims of the new Institute are to extend the application of operational research to other fields as well as industry, to bring it into closer relationship with the social sciences and to carry out fundamental research. It will encourage the development of operational research in the universities, but because operational research is essentially concerned with action, its own connexion with the world of affairs will remain close. It hopes in time to include in its programme a study of the broad problems of social and economic policy where decisions in one area affect those in another. The Institute will keep closely in touch with existing operational research groups in industry. Mr. Jessop, who is a member of the Council of the Operational Research Society, is a graduate of the Imperial College of Science and Technology, a mathematician and statistician, and has been concerned with industrial operational research since 1948. He is at present in charge of operational research in Courtaulds, Ltd., and takes up his new appointment on May 1.

The Whiting and Industrial Powders Research Council

An Industrial Powders Division has been added to the Research Council of the British Whiting Federation, now re-named the Whiting and Industrial Powders Research Council, with the view of helping manufacturers and users having powder technology problems. Valuable experience of grinding, classifying, handling, mixing and particle size analysis of powders had been gained during work on improving the manufacture and quality of whiting. (Whiting is ground, classified chalk used as filler, abrasive or chemical in some forty industries.) This work gave the Research Council a good start in extending its activities to powders in general. Members of the new Division will decide the scope of future research, but sampling, grinding, classification, flow and packing properties of powders and particle size analysis are already under investigation. A bibliography of particle size analysis, an assisted translation scheme, and the creation of a 'powder bank' of powders of genuinely known characteristics are projects that the Division will undertake. The advantages of membership include access to all the results of jointly financed research supported by Department of Scientific and Industrial Research grants, the availability of experts for consultation, and participation in an established library and information service. Further information can be obtained from the Director of Research, The Hall, Welwyn, Herts.

Survey of Audio-visual Aids in Teaching and Research

In a written answer in the House of Commons on March 1, the Financial Secretary to the Treasury, Mr. A. Barber, stated that the University Grants Committee, the Ministry of Education and the Scottish Education Department, with the approval of the Treasury, had set up a joint committee, with Dr. Brynmor Jones as chairman, to survey the present-day use of audio-visual aids in teaching and research in the pure and applied sciences in Britain. This would take into account their use in similar fields in institutions of higher education in selected countries overseas, to assess their potential usefulness and possible lines of development in Great Britain. Here 'applied science' includes medicine, dentistry, agriculture and veterinary science. The other members of the committee are: Mr. G. Barclay, Prof. W. M. Humphrey Davis, Prof. A. L. d'Abreu, Mr. D. J. Johnston, Prof. H. Lipson, Prof. E. W. Parkes, Mr. C. W. Tonkin and Prof. C. M. Yonge.

Nuclear Power for Peaceful Purposes

In written answers in the House of Commons on February 26, the Parliamentary Secretary for Science, Mr. D. Freeth, stated that the advanced gas-cooled reactor was now exporting electricity to the grid at the design net power output of 28 MW (E), and the present view of the Atomic Energy Authority as to the economic projects of this system was that given in their eighth annual report. The problems of running the Dounreay fast reactor at power levels up to 30 MW were overcome last year and the reactor had been operating at this level since October 1962. The stability of the reactor during operation, in particular, had been shown to be satisfactory, but much work remained to be done on developing large power-producing fast reactors, particularly in the field of fuel elements.

In a written answer in the House of Commons on March 5, the Parliamentary Secretary for Science, Mr. D. Freeth, stated that hitherto the Atomic Energy Authority development of thermal reactors had been concentrated on the gas-cooled graphite moderated reactors, and power stations built in Britain were of this type—the advanced gas-cooled reactor at Windscale being an advanced version of the same system. For some time the Minister for Science and the Atomic Energy Authority had been concerned about the narrow technical base on which Britain's reactor development rested, and close touch had been kept with developments abroad on various water-moderated reactors. For some five years the Authority had intensively studied such reactors to evolve a design offering good neutron economy and low capital costs and the steam-generating heavy-water type reactor was the outcome of these studies. This reactor, with boiling light-water coolant and a potential capacity for superheating the steam, utilized pressure tubes as distinct from the pressure vessels of the gas-cooled graphite reactors. For the past two years a design and research and development programme had been undertaken to ensure that feasibility and design problems could be solved. Mr. Freeth was confident that this type showed promise as an advanced water reactor and would sufficiently broaden the basis of reactor technology in Britain. There had been close collaboration and agreement with the nuclear consortia in the assessment and design of this reactor and the capital cost of the authorized prototype was £16 million, including the cost of built-in experimental facilities and a contingency against uncertainties in estimating.

Besides its joint programme with the Belgonucléaire and other Belgian firms for the *Vulcain* nuclear marine reactor (see *Nature*, 197, 650; 1963)—the costs of which, shared equally, were confidential—the Atomic Energy Authority was participating with the European Nuclear Energy Authority in the *Dragon* high-temperature gas-cooled reactors in the United Kingdom (current annual expenditure, £4·9 million) and the Maldon boiling-water reactor in Norway (current annual expenditure, £550,000). The total cost to December 21, 1962, of these projects was £10·2 million and £2·25 million, respectively; about £4·5 million of the former figure was from the United Kingdom. Construction of the *Dragon* reactor was well advanced and fuel should be loaded within the next twelve months. The international team had already carried out extensive research and development work, the results of which would be available to the participating countries. In a written answer on February 27 regarding research into protective shielding of nuclear-powered ships, Mr. Freeth stated that work was being done on the most economic form of structural shielding to prevent damage to the reactor in the event of collision, and these collision barriers, which absorbed the energy of the striking ship, were the subject of experimental work at the Naval Construction Research Establishment. Designs were also being prepared to ensure the reactor did not suffer damage if the ship grounded. Nuclear shielding against ionizing radiation followed the principles and methods adopted for land-based stations, but a special study had been commissioned to adapt these to the ship.

The Overseas Service Aid Scheme

In a written answer in the House of Commons on March 5, the Secretary for Technical Co-operation, Mr. D. Vosper, gave the total number of teachers and other educational staff subsidized under the Overseas Service Aid Scheme at December 1, 1962, as 1,607, compared with 1,025 in June 1960, mostly in East and Central Africa. Of returns to the National Council for the Supply of Teachers Overseas from United Kingdom, employers for the school year 1961–62 notified 659 British teachers (121 officially seconded) as leaving for posts in Commonwealth countries and territories excluding Canada, Australia and New Zealand, in which a further 468 took up posts. On March 1, the Secretary of State for Scotland, Mr. M. A. C. Noble, stated that returns for the two years to August 31, 1962, showed that 130 Scottish teachers went to posts in developing countries in the Commonwealth, 8 on secondment, and 15 others were seconded to posts which did not come within the official arrangements. According to a written answer from the Minister of Education, Sir Edward Boyle, on March 7, 1,232 Commonwealth teachers from overseas are receiving teacher training in the United Kingdom.

Support for Medical Research in Britain

In a written answer in the House of Commons on February 26, the Parliamentary Secretary for Science, Mr. D. Freeth, stated that the Medical Research Council had entered into an agreement with the National Research Development Corporation and three pharmaceutical firms for a programme of collaborative research on the production of a common cold vaccine. Recent work at the Common Cold Research Unit maintained by the Council and the Ministry of Health had shown that antibody production could be stimulated by the injection of particular cold viruses, but further work would be required to discover whether such injections protected against colds. The work formed part of a broader programme of virological research supported by the Council and progress depended on an adequate supply of volunteers to test the efficiency of the vaccine. In a further written answer, Mr. Freeth stated that a generous response had been received to an appeal made by Mr. W. J. Dempster, reader in experimental surgery at Hammersmith Hospital Postgraduate Medical School, for funds for work in connexion with the development of kidney grafting. Mr. Dempster's work had received continuous support from the Medical Research Council since 1950, but when, in accordance with arrangements between the Research Councils and the University Grants Committee, the Council wrote to all universities in November 1960 inquiring whether they would be willing to include in their estimates for the 1962–67 quinquennium provision for research projects hitherto financed by the Council this project was not accorded sufficient priority by the Medical School to qualify for support within the funds available. The Postgraduate Medical School, however, had already been informed by the Council that if they received insufficient funds for the 1962–67 quinquennium to maintain all the useful projects which they wished to take over, the Council would be pleased to discuss any such projects with them. In accordance with the usual practice, a reminder had been sent to Mr. Dempster three months before the expiry of his grant inviting him, if he so wished, to submit a report in application for a renewal of grant, and Mr. Dempster made his appeal the day after the Council's reminder was posted. He has since replied that he does not require further support from the Council.

New Technique for preparing Lasers

Semiconductor lasers have been produced during the past few months by a number of research organizations, including Services Electronics Research Laboratories, Baldock, and Standard Telecommunication Laboratories, Ltd., Harlow, in the United Kingdom. The method used by Standard Telecommunication Laboratories, Ltd., Harlow, for making gallium arsenide lasers is based on a technique using cleavage, and leads to the manufacture of lasers with unusually good optical properties. A flat *p-n* junction is produced by diffusion in a carefully prepared slice of very homogeneous material, and this slice is broken into laser dice by applying mechanical pressure along accurately aligned axes with a hard stylus. If the original slice has been properly prepared, the gallium arsenide can be made to cleave along optically nearly perfect, parallel faces without difficulty. The laser is completed by adding suitable electrodes and mounting on a heat sink. The new process results in good and well-finished surfaces without the usual lapping and polishing operations, and the laser dice are extremely thin, and have, therefore, excellent thermal conduction properties. Lasers, with the high standard of perfection of their optical flats produced in this way, have been found to emit light having excellent spatial and polarization coherence.

The American Museum of Natural History

With funds which, based on British standards, are large, the American Museum of Natural History is the envy of many in the museum world. The ninety-third annual report (1961–62) contains abundant proof of the forward look in museum presentation with exhibits of *Man in Space* and *Dating the Past with Atoms* (Pp. 95. New York: American Museum of Natural History, 1962). Combined, these exhibits cover a vast range of time and indicate the rapid pace of progress in science. Although the Museum is best known for exhibits inside the building the institution goes out in many ways to the public. The Museum programme "Journey into Nature", now in its third year, is broadcast every Sunday morning and its long-established extension service to schools, colleges, libraries, hospitals and children's museums makes heavy demands on the Department of Education for circulating exhibits.

The National Art Gallery and Dominion Museum, Wellington

The annual report of the National Art Gallery and Dominion Museum in Wellington, New Zealand, for the year ended March 1962 records many bequests and gifts (Pp. 24. H. 21. Wellington: Government Printer, 1962). Particular mention should be made of a valuable cash bequest by the late Mrs. Mary McLauchlan to provide a fund to help young New Zealand artists. Loans of pictures have been made to other galleries, and the Prime Minister's suite in Parliament buildings. There has been a recent upsurge of interest in systematics of New Zealand organisms and it is pleasing to note that there is a growing tendency for workers in natural history to donate type material of new species to the Museum.

The Coryndon Memorial Museum, Nairobi

The annual report for 1961–62 of the Trustees of the Coryndon Memorial Museum indicates that this institution continues to make progress under the energetic curatorship of Dr. L. S. B. Leakey (Pp. 34. Nairobi: Coryndon Memorial Museum, 1962). In order to devote himself to field work at Olduvai and elsewhere Dr. Leakey resigned the curatorship in June 1961 and was appointed honorary curator. During the study of the fossil Bovidae Dr. Leakey found that the living African Bovidae were in a great taxonomic muddle and, in consultation with living world authorities, started a re-examination of the African species. The study was based on skulls and skeletons and not only on the skins. A two-weeks safari to Bwamba Forest in Western Uganda added much valuable entomological material to the collections.

Gem Diamonds : Lecture Course and Certificate

A COURSE has been running this session at the College of Arts and Crafts, Birmingham, in the School of Jewellery and Silversmithing, on "Gem Diamonds". This course, the first of its kind to be established in Europe, is restricted to qualified Fellows of the Gemmological Association of Great Britain. Extending over thirty-five sessions, it is being given by Mr. N. Harper. The comprehensive syllabus covers crystallography, geological occurrence and genesis, mining and marketing, cutting, polishing, synthetics, etc. The course is both theoretical and practical, and those taking it will handle both rough diamonds and cut gem-stones. Organized by the Gemmological Association, those Fellows who complete the course are invited to take an examination and, if successful, will be awarded a 'Diamond certificate'. Prof. S. Tolansky, Royal Holloway College, London, has agreed to act as examiner and will set and mark the theoretical papers. The practical examination will be conducted by I. Balfour, of the London office of De Beers. The course is now in full swing and about a dozen Fellows of the Gemmological Association are expected to sit for the first certificate examination on June 5. Further information concerning the course can be obtained from the Gemmological Association of Great Britain, 2–4 Cary Lane, London, E.C.2.

Courses in Technology

FACILITIES for advanced courses in technology have greatly improved during recent years but these facilities are not generally as well known as they deserve. The publication of a *Bulletin of Special Courses in Higher Technology* by the London and Home Counties Regional Advisory Council for Technological Education is therefore welcome and meets a real need. The *Bulletin* is published in two parts: Part 1, issued in July, gives details of advanced courses held in the autumn term, and Part 2, published in December, contains information about similar courses held in the spring and summer terms (Pp. 97. London: London and Home Counties Regional Advisory Council for Technological Education. 3*s*. 6*d*., 1962). The current *Bulletin* provides particulars of more than 300 part-time (usually evening) courses and nearly a hundred full-time courses (of less than three-month duration), the subjects ranging from Boolean algebra and technical writing to photoelasticity and ultra-sonics. To illustrate the wide range of classes available to prospective students in the area, the following have been picked at random from the *Bulletin*: transistor theory, high-vacuum techniques, nuclear engineering, metrology, mathematical aids to management, the interpretation of air photographs and trade with Japan.

University News : Birmingham

DR. J. WALKER, at present reader in reactor physics, has been appointed to the newly established chair of applied nuclear science in the Department of Physics from April 1. Titles of reader have been conferred on Dr. V. G. Welsby (electrical engineering) and Dr. J. Hardwicke (experimental pathology). Dr. H. Thompson has been appointed senior lecturer in the Department of Pathology. The following appointments have also been announced: *Lecturer*, Dr. S. Garber (industrial metallurgy); Dr. I. J. Maddix (pure mathematics). *Research Fellow*, Dr. L. A. Biran (Imperial Chemical Industries Research Fellow in the Department of Medical Biochemistry and Pharmacology); H. G. Clarke (Senior Research Fellow in the Department of Neurosurgery); Dr. O. J. Fagbemi (Imperial Chemical Industries Research Fellow in the Department of Mechanical Engineering); Dr. J. Keilson (pure mathematics).

London

MR. A. V. BRADSHAW, reader in extraction metallurgy at the Imperial College of Science and Technology, has been appointed to the chair of applied metallurgy tenable at that College. Dr. R. E. Burge, reader in biophysics at King's College, has been appointed to the chair of physics tenable at Queen Elizabeth College. Dr. E. M. Crook, reader in biochemistry at University College, has been appointed to a chair of biochemistry tenable at St. Bartholomew's Hospital Medical College. Mr. B. R. Jones, senior lecturer at the Institute of Ophthalmology, has been appointed to the chair of clinical ophthalmology tenable at the Institute. Dr. E. S. Perkins, reader in ophthalmology at the Institute of Ophthalmology, has been appointed to the Semble chair of experimental ophthalmology tenable at the Institute. Dr. S. J. Wyard has been appointed to the readership in physics tenable at Guy's Hospital Medical School, and Mr. H. S. Smith, Fellow of Christ's College, Cambridge, has been appointed to the readership in Egyptian archæology tenable at University College. Titles of reader have been conferred on: Dr. R. Niedergerke (biophysics) in respect of his post at University College; Dr. B. R. Coles (physics) in respect of his post at the Imperial College of Science and Technology; Dr. J. S. Wilkie (history and philosophy of science) in respect of his post at University College.

Announcements

DR. B. R. Nijhawan, director, National Metallurgical Laboratory, Jamshedpur (India), has been elected an honorary vice-president of the Iron and Steel Institute, London, at the international symposium on "Iron and Steelmaking", recently held in Jamshedpur (India) and jointly organized by the National Metallurgical Laboratory and the Indian Institute of Metals in collaboration with the Iron and Steel Institute. Dr. Nijhawan has also been elected vice-president of the Mining, Geological and Metallurgical Institute of India.

THE following appointments to the Board of Bristol Siddeley Whittle Tools, Ltd., have been made: Sir Arnold Hall (chairman), Air Commodore Sir Frank Whittle (deputy chairman), Mr. H. Ballantyne, Mr. B. Davidson, Dr. S. G. Hooker and Mr. S. W. Mansell.

THE third international conference on "The Mössbauer Effect" will be held at the Laboratory of Atomic and Solid State Physics, Cornell University, during September 4–7. Further information can be obtained from A. J. Bearden, Laboratory of Atomic and Solid State Physics, Cornell University, Ithaca, New York.

A SYMPOSIUM on "Chemical Process Hazards with special reference to Plant Design", organized by the Institution of Chemical Engineers (North Western Branch), will be held at the Manchester College of Science and Technology during April 2–4. Further information can be obtained from A. V. Bailey, 2 Finney Drive, Wilmslow, Cheshire.

AN international conference on "Plant Tissue Culture", sponsored by the North Atlantic Treaty Organization and other agencies, will be held at the Pennsylvania State University during May 28–June 1. The programme will cover the problems of nutrition, metabolism, morphogenesis, cytology, genetics and pathology. Further information can be obtained from F. Wally Lester, Continuing Education Conference Center, Pennsylvania State University, University Park, Pennsylvania.

THE 1963 conference of the Institute of Metal Finishing will be held in Edinburgh during April 30–May 4. The programme will include the following technical sessions: aluminium coatings and anodized aluminium; internal stress in electrodeposits; nickel and chromium coatings; discussion forum on metallic coatings; organic coatings; discussion forum on organic coatings; miscellaneous electrolytic processes. Further information can be obtained from the Conference Secretary, Institute of Metal Finishing, 32 Great Ormond Street, London, W.C.1.

RADIOBIOLOGICAL INSTITUTE OF THE ORGANIZATION FOR HEALTH RESEARCH TNO, HOLLAND

ON October 23, 1962, the new laboratory building of the Radiobiological Institute at Rijswijk, Holland, was formally opened by the Minister of Social Affairs and Public Health, Dr. G. M. J. Veldkamp. This ceremony marked the completion of the new facilities of the Institute, which was founded in 1956. Besides the main laboratory building (Fig. 1) there are three animal pavilions for the mouse colony, for an *SPF*-rat colony and for a monkey colony and a separate building housing the workshop and a conference room.

The Institute, which is under the direction of Dr. D. W. van Bekkum, has a broad research programme in the field of somatic radiation effects and their modification. Radiation damage to the living cell is investigated by means of biochemical and histological techniques, using not only tissues from animals exposed to radiation but also simpler systems such as mammalian cells cultured *in vitro*. For biochemical and biophysical investigation, cloning techniques as well as suspension cultures provide large quantities of cells. The reaction patterns of these cell populations in response to radiations of different ionization density give a clue to the fundamental processes involved in cellular radiation damage. In addition, these investigations are expected to provide a theoretical basis for a more rational X-ray therapy of tumours. In order to verify the patterns observed *in vitro* under various conditions *in vivo*, parallel investigations are carried out with transplantable tumours in experimental animals.

One of the functions of the Institute is to promote the clinical application of data obtained from experimental radiobiological research. Co-operation has been established with the Rotterdam Radiotherapeutical Institute and a radiologist is working under the joint auspices of the two Institutes on subjects of direct practical interest.

A second major field of study is the prevention and treatment of radiation disease in which bone marrow transplantation in monkeys at present plays an important part. In addition, various immunological problems are being examined which are directly related to phenomena observed after transplantation of bone marrow. These more fundamental investigations are usually carried out with rats and mice. Clinical work on these problems is not performed at the Institute, but one of the staff members has a formal affiliation with the University Hospital at Leyden to organize and direct clinical studies in the field of bone marrow transplantation.

A third group of investigations concerns the toxic effects of radioactive isotopes. In recent years, emphasis has been laid primarily on the late effects of strontium-90 contamination in mice and the evaluation of various methods of treatment. The present new facilities permit an appreciable expansion of this work, both with respect to an increase in the number of experimental animals and the inclusion of other isotopes.

For some time the Radiobiological Institute has also carried out low-level determinations of radioactive isotopes in various biological products, but whenever these

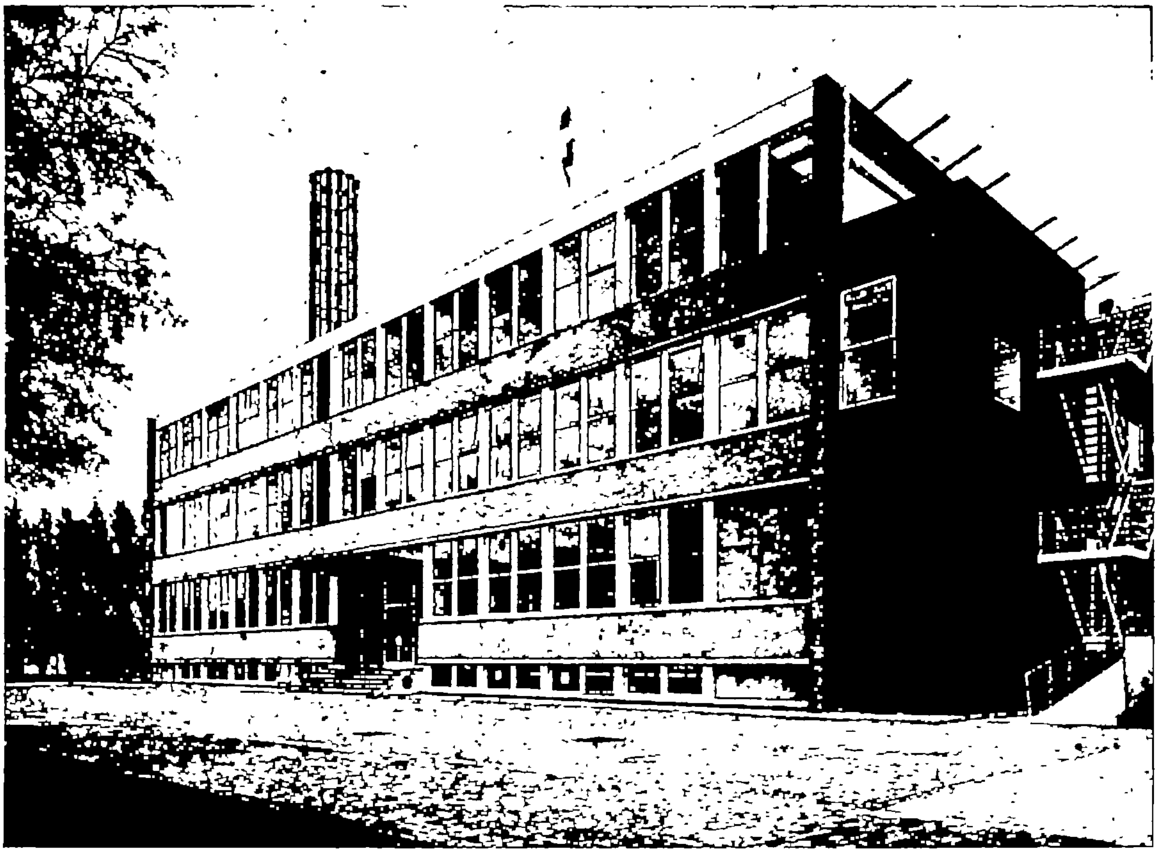

Fig. 1. Laboratory building of the Radiobiological Institute TNO, Rijswijk, Holland

determinations have become a routine they have been taken over by other groups.

The Institute is well equipped with a variety of modern instruments and apparatus for biochemical and biophysical work. In addition, the radiobiological investigations require two special kinds of facilities, namely, radiation sources and experimental animals of very high quality. The Radiobiological Institute has at its disposal, besides small α- and β-sources, a 200-c. cæsium-137 γ-source for prolonged radiation of experimental animals and a 250-kV 'Maxitron' X-ray unit with circular beam used for short-term radiation. The special tube with which this apparatus is equipped makes it possible to irradiate a number of large animals simultaneously.

Lastly, a neutron generator is in use for measurements in the field of neutron dosimetry, and with this machine small biological objects such as cultured cells or small numbers of mice can be irradiated with neutrons. Co-operation has been established with the Reactor Centre of the Netherlands at Petten, which will make it possible to expose larger experimental animals to fission neutrons.

The laboratory has four specially designed rooms for biological work with higher levels of radioactive isotopes with installations for the removal of airborne and fluid waste.

In the Institute an attempt is made to maintain unusually high standards of health in the experimental animals used for radiobiological research. This policy, in which a great deal of effort and resources is involved, is followed for two reasons. In the first place, in many experiments the animals are exposed to total-body irradiation which greatly reduces their resistance to infection. When pathogenic micro-organisms are present even without causing manifest disease symptoms, there is a risk that the animals will develop the disease after irradiation. The consequent mortality will often prevent the successful conclusion of experiments. In the second place, a very prolonged observation period is required for the investigation of the so-called late effects of radiation and of isotope intoxication. These long-term experiments usually extend over the entire life-time of the animal. In the past, the health of the ordinary laboratory animals (conventional animals) often was so poor that most of them died of specific diseases at 'middle-age' or earlier, even without being exposed to other injurious factors.

The opinion held at the Radiobiological Institute is that long-term experiments with insufficiently selected animals will result only in loss of time and money. A start was therefore made some years ago, in co-operation with the Medical Biological Laboratory RVO–TNO, on a programme of far-reaching sanitation of the animal colonies. The procedure was based on Cæsarean-delivered, hand-fed young animals raised under strict isolation. The hand-feeding has now been abandoned since gnotobiotic animals are available for foster-nursing. The experience obtained so far has led to a modified approach —which is at present being pursued—namely, a multiple-step system for the production of satisfactory animals. These steps range from heavily protected gnotobiotic animals, via specific pathogen-free stocks to lightly protected production units. In cases of infection or other disorders in the production colonies, supplementation and, if necessary, total replacement can be made with animals from the next higher step. This project receives financial support from Euratom, and one of its objectives is to determine what grade of sanitation is optimal for the various kinds of radiobiological work.

The staff of the Institute includes, in addition to two physicists and two biochemists, seven medical graduates with training in different fields.

L. M. VAN PUTTEN

THE CARNEGIE INSTITUTION OF WASHINGTON

YEAR BOOK No. 61* of the Carnegie Institution of Washington, covering the year ended June 30, 1962, and including the reports of the President, the Mount Wilson and Palomar Observatories, the Geophysical Laboratory, the Committee on Image Tubes for Microscopes, and the Departments of Terrestrial Magnetism, Plant Biology, Embryology, and of Genetics, marks the sixtieth anniversary of the Institution. The Institution's budget is now more than 2·8 million dollars, all of which is spent on six operating departments, whereas in 1905 the budget was less than 600,000 dollars, of which 302,000 dollars went to ten departments, about half of this being for the Solar Observatory on Mount Wilson, then under construction. Some 130,000 dollars were distributed in grants and nearly 30,000 dollars on subsidizing publications.

Experiments on maize had already begun, as had cytological research on *Drosophila*, and the Department of Genetics is still finding these lines of investigation productive. During the year, Dr. Barbara McClintock confirmed the hypothesis that there is a high probability that genic control systems in maize and bacteria act in similar fashion. In the meantime, the group working on the application of cytology to genetics found that direct chromosomal breakage occurs in *Tradescantia* root tips in presence of 5-bromodeoxyuridine, which acts by modifying the base sequences in nucleic acid rather than the phosphate–sugar helixes attacked by deoxyribonuclease, and that Golgi bodies, one of the types of cytoplasmic organelle, exhibit different forms in the progression of microsporogenesis in *Tradescantia*. The Department has also established the molecular weight of the deoxyribonucleic acid of a bacteriophage known as $T5$ by first establishing an ingenious pair of scales by analysing the deoxyribonucleic acid fragments of another phage ($T2$), and has found that the molecular characteristics of the deoxyribonucleic acid of phage lambda differ remarkably from those of other deoxyribonucleic acids, possessing a broad range of denaturation temperatures. The Department is now being terminated as a separate administrative unit and staff remaining in the Genetics Research Unit will co-operate with the new Laboratory of Quantitative Biology which is being organized.

In the Department of Plant Biology attention is still directed on the functions of chlorophyll and the accessory pigments in photosynthesis in which it has been interested since 1911. The persistence of the chemically unidentified material previously formed by illumination of chlorophyll *a* has been measured, and by measuring oxygen exchange of Swiss chard chloroplasts four separate effects of light, each with its characteristic action spectrum, have been distinguished. Using the new technique of electron paramagnetic resonance, two distinctly different light-induced resonances have been observed, and it is concluded that the rapid-decaying signal, seen only when cells are illuminated, is associated with chlorophyll and arises from the 'primary' act of photosynthesis. Any inhibition of oxygen evolution, as by 3-(3′ : 4′-dichlorophenyl)-1 : 1-dimethyl urea, or by limiting the manganese–ion concentration in the growing medium, produces an enhanced rapid-decaying signal. Moreover, besides the evidence that chlorophyll is the source of one type of free electrons in an intact photosynthetic organism and that plastoquinone is the site of another type, the two types of signal have been correlated with the evolution of photosynthetic oxygen. Some particularly interesting studies of the photosynthetic rates of six races of *Mimulus* originating in diverse climates and altitudes indicated that climatic races within the same species may show differential patterns of response linked with variations in internal physiology.

---

* Carnegie Institution of Washington. *Year Book*, No. 61. July 1, 1961–June 30, 1962. Pp. xi+112+526+21 plates. (Washington, D.C.: Carnegie Institution of Washington, 1962.)

The Department of Terrestrial Magnetism, in which the emphasis of the programme has markedly changed from earlier years, apart from studies of the intensity of the charged particles in the Van Allen trapped-radiation belt (as recorded during the transits of satellite *Explorer VII* through the belt between 1959 and 1960), was concerned with the application of physical techniques to a wide range of geophysical and biological problems. Using a simple and effective new procedure, it has been demonstrated that the deoxyribonucleic acid-like ribonucleic acid comprises about 1 per cent of the total ribonucleic acid of bacterial cells, and that it has a half-life during active synthesis of about 2 min. If this ribonucleic acid is, in fact, the template for protein synthesis, a single molecule acts catalytically for the synthesis of many polypeptide chains. The method can also be used to exploit the specificity in the hybridization process, which depends on long regions of complementary nucleotide sequences in molecules of ribonucleic acid and deoxyribonucleic acid and it can also be used in studies of the transcription of genetic information and of differentiation.

With support of the National Science Foundation, the Department is establishing a new Carnegie Radio Astronomy Station in Argentina, and it is also constructing an interferometer array from parabolic disk antennæ to obtain precise positions of radio-noise sources in the sky. During the period covered by the report, the observational programme in radio astronomy continued and observations of the hydrogen gas content at the centre of our Galaxy confirmed that the motions of hydrogen close to the Galactic centre are complex and that the hydrogen gas is expanding as well as rotating. A major co-operative project of the Seismic Studies Group was an intensive study of the Earth's crust in Maine which demonstrated the very real limitations imposed on our ability to learn about crustal 'layers' by the customary methods of explosion seismology, and its findings postulate appreciably less granitic material than is customarily thought to be in a continental crust. The Group concerned with the radioactive dating of rocks participated in an exchange with the Geological and Mineralogical Institute of the University of Kyoto and has compiled a new map of age-distribution in crystalline basement rocks of North America. The Department is also associated with the work of the Committee on Image Tubes for Telescopes which has now reached a stage when a real gain in research work over the best photographic plates is just beginning to be realized by means of convenient (and permanent) sealed-off image tubes.

The Geophysical Laboratory focused much of its work in experimental petrology during the year on pyroxene minerals and the study of phase equilibria at higher pressures. Additional experimental data for constructing concepts of the Earth's mantle and crust are being obtained from an examination of the melting relations of silicates at high pressures. Much effort was expended on studies of the mineralogy of meteorites, and new investigations in organic geochemistry included analysis of Precambrian carbonaceous materials. Fatty acids were isolated from rocks as old as 500 million years, including myristic, palmitic and stearic acid, and the same acids have been isolated from recent sediments but with a marked difference in the relative proportions of acids. Much the longest of the departmental reports, that from the Geophysical Laboratory, includes summaries of more than fifty investigations.

At the Mount Wilson and Palomar Observatories an extensive study of the accumulated magnetograms to classify magnetic regions and correlate them with optical and radio phenomena showed that the unipolar magnetic regions of the Sun correlate in position with the calcium absorption phenomenon observed spectroscopically. Studies of the spectra of the major planets were commenced and two lines of the hydrogen molecule were found in the spectrum of Saturn. The analysis of high-dispersion spectra of Venus afforded evidence of large changes in the temperature of the atmosphere of Venus. Colour-magnitude diagrams have been constructed for many globular and galactic clusters and high-dispersion spectra used to make detailed quantitative chemical analyses of stellar atmospheres. New knowledge was obtained about differences in chemical composition among stars, the correlation of chemical composition and star movement, and fresh evidence on the expansion of the cosmos from studies of nearby galaxies by photoelectric scanning methods. From studies of the orbits around the nucleus of our Galaxy of a large number of dwarf stars, both normal and sub-dwarf types, the time of formation of the Galaxy out of the medium of the universe has been fixed at about 10 billion years ago.

VASCULAR A

A SYMPOSIUM on the "Vascul
Responses in Injury", organize
Pathology of the newly established Fac
of the University of New South Wales,
ogists from all parts of Australia, and
the presence of Sir Roy Cameron, of U

into a central zone containing corpuscles, and a peripheral zone composed of plasma. This 'plasma skimming' is increased by the addition of substances which increase the sedimentation rate of the blood, for example, high molecular weight polymers like dextran.

Next, Dr. W. E. Stehbens (Canberra) discussed the structure of vascular endothelium with particular reference to the existence of intercellular cement substance. Carbon, chylomicra and platelets were injected into the circulation but did not stick to the space between vascular endothelial cells on electron microscopic examination. Transparent glutinous masses present in the rabbit's ear chamber, and in the frog's web after the intravascular administration of carbon, were shown to be agglutinated masses of platelets with some fibrin, rather than cement substance. Accordingly, the evidence for the existence of capillary cement substance is inconclusive.

Dr. I. K. Buckley (Melbourne) described the structure of cellular and vascular reactions after injury. Injury was produced by a high-frequency electric current to ear chamber tissue. A progressively enlarging area showed vascular damage, and nearby granulocytes migrated towards this centre of injury. Thin-walled transparent globular structures, probably myelin figures, developed at the surface of heat-injured cells.

Dr. W. J. Cliff (Perth) described electron microscopic studies of the process of wound healing in the rabbit's ear chamber. Cell division occurred near, but not at, the tip of capillary sprouts. The tip of the cord consisted of a mass of endothelial cells, which gradually separated; the lumen was constituted by the intercellular space so formed. Basement membrane was probably produced by interaction between endothelium and the extravascular tissues, while both adventitial cells and smooth muscle cells probably developed from fibroblasts.

The session concluded with a report on the reaction of cells of peripheral and intermediate lymph to foreign
materials by Dr. J. G. Hall (Canberra), read in his absence
by Dr. B. Morris. Foreign materials were injected into
he hind limb of a sheep the popliteal lymph node of which
ad been cannulated on either the afferent or efferent
de. Radioactive isotope studies showed that a non-
rticulate antigen—human globulin—was not retained
the lymph node, whereas a particulate antigen, the
an red cell, was. About 50 h after the initial injection
cell population of the efferent lymph from the node
change: initially, large immature cells poured
ph, followed later by lymphocytes and plasma
tput of RNA correlated quite closely with
l response.

sion was given over mainly to the
ated with inflammation. The session
Roy Cameron (London), who described
ellular events following injury.

ns to injury are chemically mediated,
e, aided in some species by 5-hydroxy-
inning of increased permeability is

more complex. These
lasma factors—kinins
and antagonized by
ugmented hist-
ve loss of

dense the fraction the smaller the lipoprotein particle. The smaller molecules passed across the membrane more readily than the larger. After heat injury in hyperlipaemia, there was an increase in the lipids in the lymph, which may become milky. It is postulated that materials pass through the capillary wall in vesicles or otherwise and that the polysaccharides in the basement membrane act as a sieve. After injury, in hyperlipaemic animals, lipoproteins also passed across the endothelium in arteries, and were deposited below the internal elastic lamina.

Vascular permeability changes in ultra-violet injury were described by Dr. G. Logan and Prof. D. L. Wilhelm (Sydney), using the technique of 'blueing'. In ultraviolet, as in other types of injury, the inflammatory reaction is characterized by three vascular responses—vasodilatation, increased permeability and migration of leucocytes. In this case, however, they develop relatively slowly and can be dissected apart. Erythema and increased permeability each occur in two phases: the leucocytosis rises and falls 3–4 h in front of the late phase of increased permeability. The early phase of increased permeability is mediated by histamine in guinea pigs and rabbits, by 5-hydroxytryptamine in rats. The mediator of the late phase is unknown.

Dr. J. Margolis (Sydney) gave an account of his quantitative work on plasma kinins. These factors may be released from plasma by kallikrein, trypsin or the glandular 'kallikreins' from saliva and urine. The normal release of these factors is dependent on three factors: component *A*, or kallikreininogen; Hageman factor, which is also involved in blood clotting; and compound *B*. a protein easily adsorbed on to glass. Hageman factor is easily activated by contact with a negatively charged surface. Trypsin and the glandular kallikreins are independent of the Hageman factor.

The plasma kinins are bradykinin, a nonapeptide, and kallidin, a decapeptide. These may be loosely attached to plasma globulins as kininogens; plasma kallikrein may act on one substrate (globulin plus nonapeptide) corresponding to the nonapeptide precursor compound *B*. The others act on both substrates (globulin plus nonapeptide, and globulin plus decapeptide); trypsin produces bradykinin, and glandular kallikrein produces both the nona- and deca-peptides. The decapeptides are attacked by a plasma peptidase to produce a nonapeptide which is probably bradykinin.

The last paper of the day was given by Dr. B. Morris (Canberra). He described techniques for producing permanent lymphatic fistulæ in sheep. The blood vascular and lymphatic flow in an area are both altered by exercise. Thus, exercise induces a cessation of flow of intestinal lymph and a fall in hepatic lymph flow, but an increase in the flow of leg lymph. In the exercised lactating sheep mammary flow increases. Exercise also increases the rate of turnover of radioactive protein between the intravascular and extravascular compartments.

The main topic of the third session (November 3) was the response of cells in inflammation. Dr. J. V. Hurley (Melbourne) demonstrated the existence of an active principle which induces leucocytic migration. This substance may be derived from burn extracts, from polymorphs and from activated serum; it is non-dialysable, is destroyed
ut not by ethylenediamine tetraacetic acid
rmeability inhibitors.

tion of how cells recognize one another
viour is controlled by other cells was
. V. Boyden (Canberra). The chemo-
he first part of the recognition of foreign
vestigated. Cells were observed while
gh a millipore collodion membrane
material on the other side; the more
rial, the greater the tendency for the
rate towards it. In the case of cellulose
gration was much more marked in the

presence of serum. It was concluded that the power of recognition of the foreign material lay not in the cells but in the serum.

Dr. V. J. McGovern (Sydney) reported on work carried out in collaboration with Dr. D. Bloomfield. The ability of leucocytes to stick to vascular endothelium was investigated using *en face* preparations. Saline was injected into the adventitia of arteries, and 1·5–3 h later leucocytes stuck to the uninjured endothelial surface. These penetrated the endothelium and continued to do so until about 18 h after the original trauma. If in making the injection the endothelium was injured to the point of thrombosis, or nearly so, leucocytes stuck to the endothelium much more rapidly. The worse the injury, the sooner did they stick.

The structure of macrophages was the subject of an account by Dr. I. Carr (Sydney). The common feature in granulomata induced by introduction of foreign materials was the presence of spherical masses of phagocytic cells arranged around the foreign material. It was suggested that lipid was phagocytosed in these circumstances by a process which involved the membrane disappearing and the material passing into the cell free of membrane. The hypothesis was put forward that the cell membrane may dissolve in the extracellular lipid. The giant cells in these lesions probably are formed largely by cell fusion.

The last paper was that of Dr. E. G. Cleary (Sydney). Dr. Cleary described his analysis of the content of collagen and elastin in samples of human arterial intima and media. More elastin was present proximally and more collagen distally, but the sum of these was constant. The elastin content was probably increased in the new-born; collagen decreased with age. Even muscular arteries were found to contain as much as 52 per cent collagen by chemical analysis.

In his summing up, Sir Roy Cameron commented on the wide range of interest of the symposium, which indicated the emergence of a distinctive Australian approach to experimental pathology.

GELATINE AND GLUE RESEARCH

The twenty-fourth research panel meeting of the British Gelatine and Glue Research Association was held at the Strand Palace Hotel, London, W.C.2, on November 7. The chairman of the Association, Mr. S. G. Hudson (Richard Hodgson and Sons, Beverley), presided and directed attention to the place of the first paper on wool structure in the research panel series, which has lately included papers on other complex proteins such as collagen[1] and elastin[2].

Dr. A. Robson (Wool Industries Research Association, 'Torridon', Leeds) contributed a paper on "The Sulphur Balance in Wool". In the past it has often been noted that total sulphur analyses for wool are significantly larger than the sum of the individual sulphur-containing compounds estimated by other methods. Most of the sulphur in wool is in cystine, and colorimetric and chromatographic assays of cystine in wool hydrolysates differ by 10 per cent. This fact caused the problem of the sulphur balance to be re-examined. Hydrolysates of wool labelled with sulphur-35 were chromatographed and found to contain several unidentified sulphur compounds, of which one became very abundant when hydrolysis was prolonged. It was identified as *bis* (β-amino-β-carboxyethyl) trisulphide, that is, the trisulphide analogue of cystine[3]. Thus some of the cystine decomposes during wool hydrolysis and from careful analyses it is concluded that wool contains sulphur only in the form of cystine, cysteine and methionine, thus bringing it into line with other proteins and removing the discrepancy in the sulphur balance. The discussion centred around the mechanism by which the trisulphide artefact might be formed.

In the second paper, Mr. L. J. H. Slack (English Abrasives Corporation, Ltd., Tottenham, London, N.17) discussed "Comparisons of Natural and Synthetic Glues in the Coated Abrasives Industry". The industry is a key one in relation to many others of much greater size, for example, metal working. There is a considerable variety of coated abrasives and the glues used include hide glue and synthetics based on alkyds, urea, melamine and phenols. The merits and demerits of hide glue were discussed, and it was concluded that there was need for improvement of the final film properties to enable the natural material to maintain its competitive position.

The director of research, Dr. D. A. Sutton, reported on "Some Recent Impressions of the American Gelatine and Glue Industry". Emphasis was laid on the speed and hygienic control which are characteristic of the production of American pigskin gelatine; these factors are reflected in the quality of the final product. The plants and processes used were briefly outlined and the other types of gelatine produced were commented on. Attention was directed to the extent to which hide and bone glue production are mechanized in the United States and this factor enables natural glue to be sold at a low price in spite of very high labour rates. There is no central research organization parallel to the British Gelatine and Glue Research Association, but many large companies have large well-equipped laboratories covering all their products and including facilities for gelatine and glue.

THE BRITISH LEATHER MANUFACTURERS' RESEARCH ASSOCIATION

An outstanding feature of the past year was the strengthening of contacts between the British Leather Manufacturers' Research Association and the footwear industry. The great value of these contacts lies in showing the Research Association how it can adjust its research programme to help the leather industry to meet the requirements of its main customer and they ensure that the Association's work is relevant to the present needs of the footwear industry. The demands made on leather arising from the heat and steam lasting of shoe uppers, for example, are being met and these new methods, which have great advantages, have been established and are likely to increase. A great deal of work has been done on the assessment of different leathers and finishes for these new treatments.

Investigations of skin proteins have continued at the Association's research laboratories, Milton Park, Egham, Surrey, but new emphasis is being given to seasonal variations in lambskins. The methods developed in this long-continued study of the constituents of skin have also been applied to the examination of deteriorated leathers under a research project sponsored by the U.S. Department of Agriculture. New work has been the application to collagen and certain tanned collagens of principles and techniques developed by workers in investigations of rubber-like elasticity and the cross-linking of large molecules. Determinations have been made of the number of cross-links (per unit weight) and the relative stabilities of cross-links in collagen tendons tanned with certain aldehydes. It is gratifying to record this beginning of an experimental study of a fundamental question in the theory of tanning and note that glutaraldehyde, first advocated as a tanning agent by the Department of Agriculture, Eastern Regional Laboratory, has been found very effective in producing stable cross-links. Work on curing, enzyme de-woolling and pigment finishing continues.

For many years the Research Association has given forewarnings of the problems facing the industry from effluent disposal. Recent legislation has justified these warnings to the full. Throughout Great Britain, members are steadily adopting the Association's advice to "reduce, replace and re-use". Conditions vary from tannery to tannery so that no one method is likely to be generally applicable, but amounts of lime and sulphide can sometimes be reduced without loss in quality, a proportion of the sodium sulphide normally used can be replaced by caustic soda, and the re-use of lime and chrome is practised on a wider scale. The acute problem of destroying sulphide in effluent has been tackled on a broad front and the costs of various processes for the removal of sulphide have been compared. In addition, the work of the British Leather Manufacturers' Research Association on the behaviour of tannery effluents in biological treatments is proving of immense help in negotiations with local authorities.

Income for the year 1961–62 was £88,698, an increase of £9,400 over the previous year; expenditure was £88,816.

POLARIZATION OF RADIO SOURCES AND FARADAY ROTATION EFFECTS IN THE GALAXY

By F. F. GARDNER and J. B. WHITEOAK

C.S.I.R.O. Division of Radiophysics, University Grounds, Sydney

IN two previous communications[1,2] observations of linear polarization in the radio emission from a number of extra-galactic sources were reported. The first, by us, gave details of the detection of linear polarization of the radio emission from seven out of nine sources observed at 20 cm. The result is strong support for the hypothesis that the emission originates in synchrotron radiation. A number of these sources were known to be doubles, and in several cases the E-vector of the 20-cm radiation was aligned with the direction of elongation of the source. However, it was pointed out that, owing to the possibility of Faraday rotation, the position angle of the E-vector at a single wave-length cannot be used to infer the intrinsic polarization of the source, which on the synchrotron hypothesis[3] is approximately perpendicular to the magnetic field.

The second note, by Cooper and Price[2], was directly concerned with Faraday rotation. It was found that for three selected points in the radio source Centaurus A the received polarization progressively rotated with increasing wave-length at a rate proportional to the wave-length squared. This is in agreement with Faraday rotation, for which the rotation θ in radians at a wave-length λ metres by a medium of electron density N per cm^3 and longitudinal magnetic field B_L in gauss is given by:

$$\theta = 8{\cdot}1 \times 10^5\ \lambda^2 \int N B_L \, dL$$

where L is measured in parsecs. We shall call the value of θ/λ^2 in radians/m^2 the rotation measure for the source. It measures the integrated value of the product of electron density and longitudinal field along the path from the

and sparse phenocrysts (plagioclase, quartz, magnetite and orthopyroxene) set in a matrix of glass and mineral dust. The dust is mainly cryptocrystalline and the pumice vesicles are coated with an unidentified birefringent material. Within the lenticles various pumiceous textures, ranging from fibrous to microvesicular, are seen. Textures characterized by globular and distorted vesicles are seen in some thin sections where fibrous pumice lenticles are cut obliquely or transversely. These textures are the same as those illustrated in photomicrographs by Steiner[5] and by Hjelmquist[10]. They can be seen in pumice of non-ignimbritic origin also.

Examination of crushed specimens in oils shows conclusively that the so-called 'globules' interpreted by Steiner as evidence of immiscibility in the Waikino ignimbrite are not a separate glass phase but merely drawn out or distorted gas vesicles within the pumice lenticles. In specimens from different parts of an outcrop the refractive index of the glass matrix may differ from 1·500 ± 0·002 to 1·503 ± 0·002, and individual lenticles may differ from others by as much as 0·002. No truly contrasting glasses corresponding to Steiner's mesostasis, base, or globules could be found, however, by us. Wherever strong Becke lines were observed, either in thin section or crushed fragments; they were between glass and rounded vesicles filled with oil or mounting media.

Similar results were found in glassy specimens from 20 different ignimbrites in a current study of the Taupo Volcanic Zone[8]. Only one multiglass ignimbrite has been recognized:

The Murupara Gorge Ignimbrite of the Meseta Central Type. An exceptional rock composed of intermingled acid and intermediate glass shards and pumice is exposed at a proposed dam site seven miles south of Murupara, New Zealand. This deposit, here called the Murupara Gorge ignimbrite, is similar to the multiglass welded tuffs of Costa Rica described by Howel Williams. It is known only at this type locality, overlying the extensive Waitaha Ignimbrite Group[9]. It is 70 ft. thick and consists of buff to grey pumice tuff, uncommonly glassy throughout. The top and base of the sheet are non-welded; the central part is lightly welded.

Pumice fragments up to 2 in. long comprise about 35 per cent of the rock. They are slightly flattened and lie sub-horizontally in the welded zone. Black and white pumice fragments are nearly equal in quantity. The white pumice appears to have resisted flattening more than the black. Their indices of refraction are 1·498 ± 0·002 and 1·538 ± 0·002 respectively.

The tuff is a compressed sinter of colourless and brown glass shards corresponding to the white and black pumice. The ratio of colourless to brown shards is about 2 : 1; their refractive indices are 1·498 ± 0·002 and 1·530 ± 0·003 respectively. Shards are mainly one colour or the other, but approximately 5 per cent are composite, consisting of both colourless and brown glass with no distinct boundary between. Many of intermediate colour and refractive index also occur.

Phenocrysts comprise 7 per cent by volume, in the following proportions: quartz 2·5 per cent, plagioclase 87 per cent, orthopyroxene 6·5 per cent, and magnetite 4 per cent.

Although a few recent papers have tended to emphasize the alleged existence of separate glass phases in ignimbrites or the possibility of immiscibility in igneous lavas, it is cautioned that the presence of more than one glass in these rocks is very rare. In the case of the Murupara Gorge ignimbrite, which appears to have been formed by simultaneous pyroclastic eruption of acid and intermediate magmas, the presence of individual multicoloured shards, and those of intermediate refractive index, refute any suggestions of immiscibility between these parent magmas.

INHIBITION OF THE BIOLOGICAL ACTION OF THYROID HORMONES BY ACTINOMYCIN *D* AND PUROMYCIN

By Dr. J. R. TATA
National Institute for Medical Research, Mill Hill, London, N.W.7

THE stimulation of basal metabolic rate induced by thyroid hormones has often been attributed to an alteration of the efficiency of oxidative phosphorylation by direct interaction between the hormone and mitochondrion[1]. It has recently been shown by us that, when administered in small amounts, thyroid hormones cause an early and substantial increase in the rate of protein synthesis by both microsomes and mitochondria, without any of the direct effects on mitochondrial function described earlier[2,3]. We suggested, therefore, that both the calorigenic and growth-promoting actions of thyroid hormones (and probably other multiple biological actions, as well) are secondary manifestations of a primary action at the cellular level which influences the rate of protein synthesis. I have recently obtained further evidence which supports this suggestion.

It has been shown that actinomycin *D* inhibits protein synthesis by suppressing the formation of messenger RNA (ref. 4) whereas puromycin inhibition occurs at the stage of assembly of new protein at the ribosome[5]. Starvation suppresses protein synthesis by depriving the synthetic machinery of essential amino-acids as well as by lowering the level of RNA in the cell[6]. The effect of each of these inhibitory agents on the physiological response to the thyroid hormones, L-thyroxine and 3,5,3′-triiodo-L-thyronine, has been measured. The results indicate that stimulation of protein synthesis is an essential requirement for the full physiological response to thyroid hormone, and that direct action of hormone on mitochondrial respiration and phosphorylation is not an adequate explanation of the increased basal metabolic rate observed after administration of the hormones. The effect of actinomycin *D* in particular also suggests that thyroid hormones may act by controlling the availability of messenger RNA rather than by direct stimulation of protein synthesis.

Fig. 1 shows the effect of a small dose (26 μg/100 g body-weight) of triiodothyronine on basal metabolic rate and on growth-rate of thyroidectomized rats, either in the presence or in the absence of actinomycin *D*. In the absence of this inhibitor of protein synthesis, the hormone caused a 30–40 per cent increase in basal metabolic rate over the control values and a substantial acceleration of growth rate. Actinomycin *D* alone (8 μg/100 g) caused an immediate fall of 10–20 per cent in the basal metabolic rate and a corresponding drop in body weight. The loss in body-weight is due, at least in part, to a substantial reduction in food intake. When triiodothyronine and actinomycin were given together, the calorigenic action of the hormone was entirely abolished and there was, likewise, no hormonal effect on body-weight. The growth and basal metabolic rate depressant effects of the antibiotic, in the doses used, lasted for only 4 or 5 days and the animals also developed a tolerance to further or more toxic amounts. It was therefore not practical to study the effect of pretreatment with actinomycin *D* on the biological action of a single dose of thyroid hormones.

Results similar to those shown in Fig. 1 were obtained when thyroxine replaced triiodothyronine or by using intact rats of either the Wistar or hooded strains. The differences lay essentially in the steepness of the curves of changes in growth or basal metabolic rate as a function of time. If deoxyguanosine, which complexes strongly with actinomycin *D* (ref. 7) was administered in the molar ratio of 2,500 : 1, 3 h after the antibiotic, the inhibitory effect was diminished to the extent of 20–30 per cent. Actinomycin *D* did not affect the stimulation of basal metabolic rate caused by administration of 2,4-dinitrophenol. This suggests that it acts specifically by preventing the stimulation of protein synthesis which is the normal response to small amounts of thyroxine or triiodothyronine. So far as is known, at the extremely low doses of actinomycin *D* we have used, it can only do this by inhibiting the synthesis of messenger RNA (ref. 4). The possibility therefore arises that thyroid hormones stimulate protein synthesis by regulating somehow the level of messenger RNA at the site of protein synthesis.

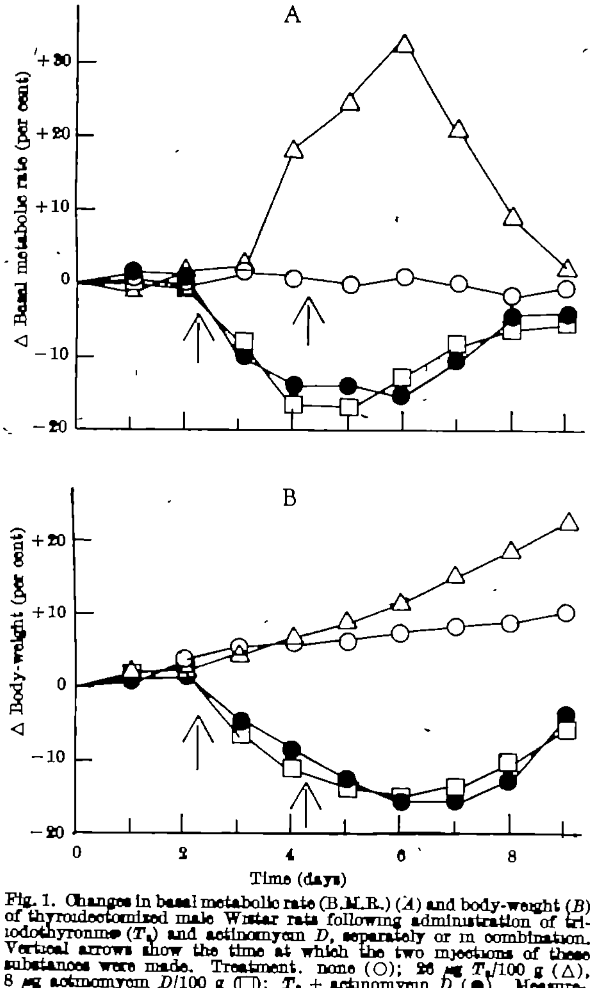

Fig. 1. Changes in basal metabolic rate (B.M.R.) (*A*) and body-weight (*B*) of thyroidectomized male Wistar rats following administration of triiodothyronine (T_3) and actinomycin *D*, separately or in combination. Vertical arrows show the time at which the two injections of these substances were made. Treatment. none (○); 26 μg T_3/100 g (△), 8 μg actinomycin *D*/100 g (□); T_3 + actinomycin *D* (●). Measurements were made individually on four animals per group. Values are expressed as change from the averages for each group on day 0, when B.M.R. = 0·54 ± 0·04 ml. oxygen/g/h and body-weight = 130 ± 4 g (compared with a B.M.R. of 0·72 ± 0·06 ml. and body-weight of 250 ± 12 g for intact controls). T_3 was injected subcutaneously, while actinomycin *D* was given intraperitoneally

Table 1. Effect of Actinomycin *D*, Puromycin and Starvation on the Triiodothyronine (T_3)-stimulated Basal Metabolic Rate (B.M.R.) and Body-weight in Thyroidectomized Rats

Treatment*	Dose of antibiotic (μg/100 g)	Change after 72 h† (per cent) B.M.R.	Body-wt.	Inhibition of T_3 effect (per cent)
None	—	± 1·5	+ 5·4	—
34 μg T_3/100 g	—	+35·5	+ 7·8	—
Actinomycin *D*	8	−14·0	−13·2	—
Actinomycin *D* + 34 μg T_3	8	−13·8	−14·1	100
Puromycin	12,000	+ 1·0	− 7·7	—
Puromycin + 34 μg T_3	12,000	+ 9·8	− 6·0	69
Starvation	—	+ 2·1	−16·8	—
Starvation + 34 μg T_3	—	+ 5·9	−19·0	84

* Injections were made on day 0 and again 48 h later; T_3 was injected subcutaneously and the antibiotics intraperitoneally.

† The values are based on the differences in B.M.R. and body-weight just before treatment was begun and 72 h after treatment. Actual initial values were: B.M.R. = 0·52 ± 0·04 ml. oxygen/g/h; body-weight = 125 ± 6 g.

As shown in Table 1, administration of puromycin or starvation both suppressed the calorigenic action of triiodothyronine to a considerable extent. The drop in body-weight during 72 h of starvation was 2–3 times that caused by the administration of either antibiotic. Unlike actinomycin *D*, neither puromycin treatment nor starvation alone lowered the basal metabolic rate below the levels observed in thyroidectomized animals. Over a thousand times more puromycin than actinomycin *D* was necessary to produce a comparable inhibition of thyroid hormonal activity. Such a dose relationship is compatible with the different mechanisms of inhibition of protein synthesis by these two antibiotics[4,5]. It is also significant that thyroid hormone-dependent stimulation of amino-acid incorporation into protein as well as the increased activities of some enzymes were abolished in starved animals[1,6].

In conclusion, a normal functioning of protein synthetic mechanism is essential for thyroid hormones to elicit their calorigenic and growth-promoting actions. Such a requirement may also apply to other hormones such as insulin, growth hormone and testosterone[9]; actinomycin *D* has also been shown to block some actions of cortisone[10]. In any event, the foregoing results corroborate our suggestion made elsewhere that the stimulation of total-body oxygen consumption by thyroid hormone is likely to result from an increased synthesis of some mitochondrial respiratory constituents[1,2]. A direct or indirect regulation of the synthesis or turnover of certain cellular constituents may also underlie the multiple biological actions of thyroid hormones, provided that there is a high degree of specificity with respect to the particular nucleic acids or proteins the turnover of which is being affected. An important question arising from the present investigation is to determine to what extent the inhibition of thyroid hormone action by actinomycin *D* reflects a primary hormonal regulation of the genetic informational mechanism or a less specific effect of a disturbed pattern of protein synthesis, regardless of the level at which the disturbance may take place. A study of isolated nuclei and other cell-free preparations, similar to those we have initiated for the physiological action of thyroid hormones at the cell level[1,2], may provide an answer.

I thank Prof. E. Boyland for a generous gift of actinomycin *D* and Mr. A. J. Bell for assistance.

PERIODIC NATURE OF SPONTANEOUS PERIPHERAL NERVOUS SYSTEM ACTIVITY

By Dr. A. A. ALEXANDER, Prof. ROBERT ROESSLER and Dr. NORMAN S. GREENFIELD

Wisconsin Psychiatric Institute and Department of Psychiatry, University of Wisconsin

RHYTHMIC central nervous system activity and spontaneous autonomic nervous system activity are well documented[1,2]. The literature relating the central and the autonomic nervous systems function is also quite extensive (cf. review by Dell and Bonvallet[3]). Yet, little is known of rhythmic activity in peripheral nervous system functions (cyclic fluctuations in variables such as heart rate or skin temperature are usually specified on the order of hours rather than minutes or seconds). It was therefore predicted that relatively high-frequency rhythmic activity could be discerned in measures mediated by peripheral physiological systems.

This hypothesis was tested by means of a variance (or power) spectrum analysis of resting-levels of the psychogalvanic response, finger blood volume, heart rate and electromyograms. The power spectrum is the integrated Fourier transform of the auto-correlation function of a time series[4,5], and allows an estimate of the variance at each of a series of frequency intervals. 6 min of continuous data were scored at every second for each of the four measures on each of 40 subjects. Power spectra of each 360-sec series were then derived on a CDC 1604 computer, following the formulæ of Blackman and Tukey[6]. Sixty computational lags were used allowing the examination for periodicity at each of 60 frequency-intervals. The frequencies studied ranged from 0·5 c/s to 0·008 c/s. Their reciprocals, or periods, range from 2 sec to 120 sec. Periodicity, when present, was indicated by a hump in the spectrum when plotted as the proportion of the total variance per frequency interval (Fig. 1). The degrees of freedom appropriate to evaluating the significance of any such hump was 12, and, based on a χ^2 distribution and a Gaussian assumption, the value at the top of the hump had to exceed that of the bottom of the valley by a factor of 4, to differ at the 95 per cent level of confidence. Humps greater than valleys by a factor of 2 would differ at the 80 per cent level of confidence.

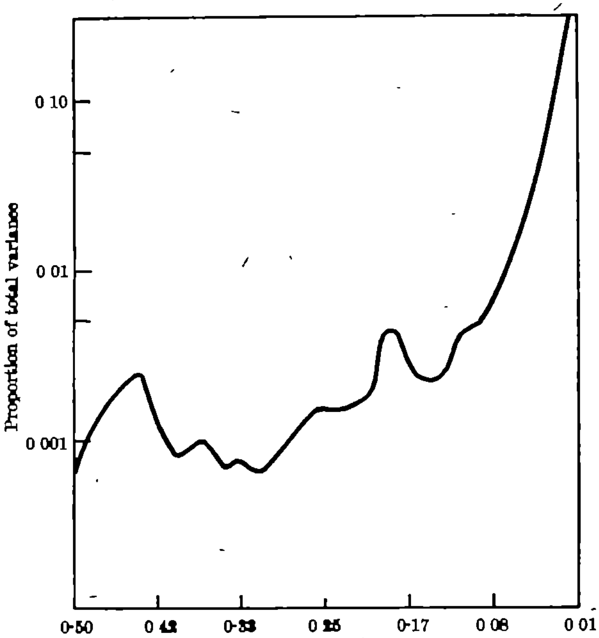

Fig. 1. Average power spectrum of finger blood volume. No. = 40

The 6 min of each variable scored were taken after a 15-min period in which the subject had been asked to relax with his eyes closed, while alone in a sound, temperature and humidity regulated test room. Heart rate was scored to the nearest beat per minute; finger blood volume, taken from the forefinger of the left hand, to the nearest 0·1 c.c.; psychogalvanic response, taken at the palm of the left hand, was accurate to 1 per cent of actual ohms resistance, and the frontalis electromyogram to the nearest 5 mV. Subjects were taken from a larger group and were composed of 20 psychiatric in-patients and 20 non-patient volunteers, balanced for sex, in an age-range of from 15 to 34 years. Subjects under heavy drug doses, or exhibiting any organic involvement, were excluded from the analyses.

Most spectra showed an overall upward trend of variance as the length of the period increased—indicating an adaptation effect over the 6-min period from which the spectra were derived. Cyclical changes over and above the long-term changes were of primary interest, however, so each spectrum was examined separately for the presence of peaks more than twice the variance of the base-line. One subject of the 40 did not exhibit any periodicity on any of the four physiological measures. Thirty-eight of the 40 subjects exhibited periodicity on heart rate; 33 of these in a 2–7 sec range were cyclical fluctuations which correspond with respiration. It is likely that this observed arrhythmia is a reflex regulation of heart rate initiated at least in part by pulmonary receptors in the chest wall stimulated by expansion[7]. As such they would not reflect entirely spontaneous, centrally mediated rhythms, so such periodicities were not included in the following determination. (The ability of the power spectrum programme to pick up the well-known sinus arrhythmia effect is, however, an indicator of its efficacy.) Other than heart rate periodicity in the range excluded, four subjects were not periodic in any of the other three variables examined, bringing to a total of five the subjects who were not periodic in any variable. Therefore, 87·5 per cent of all subjects tested were periodic in one or another of the physiological variables recorded. The periodicity of 20 of these 35 subjects was of a magnitude four times the base-line.

The five subjects whose spectra did not peak on any of the variables sampled were possibly periodic at periods longer than those the power spectrum could discern. This notion is supported by the fact that the greatest portion of the variance was often at 120-sec periods, the longest the programme could examine, and the variance at this point was greater than that for the infinite period.

Eighteen of the forty subjects were periodic on the electromyogram spectra; the period at which humps occurred ranged from 2 sec to 60 sec with an approximately even distribution across this range.

Twenty-three of the total number were periodic on finger blood volume; the range was again from 2 to 60 sec periods. Most of the periodicity was at high frequencies, however, only three subjects having periods greater than 10 sec (10, 13 and 40 sec).

Eight subjects were periodic on psychogalvanic response—the longest period was one of 15 sec.

As indicated previously, there were five subjects who were periodic on heart rate at a frequency which could not be accounted for by respiration rate (for example, periods of 45 sec or 2 sec).

The differences between individuals, with respect to the variables on which they were periodic, is consistent with the growing body of literature dealing with individual 'stereotypy'—the tendency for a given individual to respond to a number of stimulus situations with a characteristic autonomic variable[8].

The presence or absence of periodicity did not bear any consistent relationship to other physiological scores such as mean level or variance. The presence of periodicity in electromyograms was associated with higher mean electromyogram-levels. However, subjects exhibiting finger blood volume periodicity had generally higher mean volumes than did subjects non-periodic on the measures—contrary to what might be expected if periodic function was concomitant with arousal. Mean heart rate and psychogalvanic response differences between subjects periodic and non-periodic on each of these measures were not significant. Analyses by psychiatric and control groups and various psychological measures in relation to frequency of periodicity will be reported later.

EVIDENCE FOR MULTIPLE CALCIUM POOLS IN THE BLOOD OF DOGS

By MILDRED J. WIESTER, SUSAN H. WHITLA and Dr. RICHARD GOLDSMITH

Radioisotope Laboratory, Veterans Administration Hospital, Cincinnati, Ohio

IN the course of investigating thyroparathyroidectomized dogs after a single injection of calcium-45, a considerable difference in the specific activity of blood and urine was observed. While most of the results obtained will be reported elsewhere, the specific activity ratio for blood and urine are discussed in this report. Likins and Craven previously reported an apparent difference in the renal clearance rates for calcium-45 and calcium-40. They studied fasting and fed rats[1]. Dow and Stanbury reported examination of human beings, utilizing a single injection of calcium-45, during which they noted specific activity ratios of blood to urine which were approximately 1·5 (ref. 2). They compared the specific activity of serum collected at time *t* with that of urine collected over an interval from time *t* to some later time t_1. The results presented here concern observations made on a single thyroparathyroidectomized dog and suggest that the various forms of calcium present in blood equilibrate with calcium-45 at different rates. Similar, but less-significant, differences were observed in normal dogs.

A thyroparathyroidectomized male dog, weighing 35 lb. and maintained on 0·1 mg of thyroxine per day, was used. The dog was injected intravenously with 17·5 μc. calcium-45 (specific activity of 478 μc./mg calcium-40). 36 h later oral intake was limited to water. The dog was anaesthetized with 'Nembutal' 48 h after administration of calcium-45. A catheter was inserted into the bladder for urine collection and an arterial needle was placed in the femoral artery. An infusion of an isosmotic solution containing creatinine and mannitol was started in order to produce an osmotic diuresis and to allow for calculation of the glomerular filtration rate. About 30 min after the start of the infusion, a 60-min urine collection was initiated. Arterial blood was collected over heparin at the mid-point of this collection. At the end of the first urine collection, calcium chloride labelled with calcium-45 was added to the infusion (0·13 μc. calcium-45 and 15 mg calcium-40/min). Three subsequent hourly urine collections with appropriate arterial blood samples were obtained.

Chemical calcium analyses were performed on urine, plasma, plasma ultrafiltrates and on trichloroacetic acid (TCA) filtrates of plasma by a modification of the method of Collip and Clark[3]. Plasma ultrafiltration was performed by Toribara's method[4]. The error for these determinations was 2 per cent (at least 3 aliquots of each specimen were analysed). Creatinine was determined in plasma and urine by the method of Bonsnes and Taussky[5]; clearance studies were conducted as described by Steiner *et al.*[6]. Calcium-45 counting was performed using a gas-flow counter as described by Goldsmith (unpublished results). Plasma calcium values used to calculate specific activity were obtained from analysis of the TCA filtrate since calcium-45 counting was performed on TCA filtrates of plasma. Phosphorus determinations were performed according to Fiske and Subbarow[7] to establish a basis for calculation of the tubular re-absorptive capacity for phosphorus.

These investigations were conducted on one of a series of animals similarly operated. These animals separate into two groups soon after surgery, one demonstrating normal and one abnormal blood calcium and phosphorus concentrations[8]. This particular animal was one with normal blood mineral values from the second postoperative week. Hypoparathyroidism was probable, despite normal chemistries, since subsequent re-exploration of the neck area did not disclose (grossly or by serial sections of paratracheal tissue removed) parathyroid tissue and since measurement of phosphorus clearance and re-absorption gave values expected in hypoparathyroidism. As seen in Table 1, not only was the initial value for the tubular reabsorption of phosphorus high, it failed to increase as the serum calcium concentration rose with the infusion of calcium 40. This has been considered evidence of hypoparathyroidism in man[9]. The ratio of the phosphorus clearance to the creatinine clearance increased during the period of calcium infusion (in 2 of 3 collections). This, too, is suggestive of the absence of parathyroid hormone secretion[9]. Table 2 contains the chemical calcium concentrations of each specimen. The plasma ultrafilterable calcium concentration increased with the increase in total calcium, but the partitioning remained relatively constant. Table 3 contains the radioactivity clearance data. The glomerular filtration rate decreased as the plasma calcium concentration increased, as reported elsewhere[10]. Before labelled calcium was added to the infusion the bladder urine had a specific activity only 55 per cent that of the simultaneously obtained plasma ultrafiltrate. The same general relationship was maintained throughout the infusion but the urine specific activity increased to 71 per cent of that of the simultaneously obtained plasma ultrafiltrate after 3 h. The ratio of total plasma/plasma ultrafiltrate specific activity was less than one at the outset of the infusion of labelled calcium but approached one during infusion. The ultrafiltrate specific activity (considered synonymous with the glomerular filtrate specific activity) increased as expected during the constant infusion of labelled ionic calcium.

Table 1. PHOSPHORUS CLEARANCE DATA

Time (min)	0–60	60–120	120–180	180–240

* Plasma ultrafiltrate is assumed identical to glomerular filtrate.
† Derived values.
GFR, Glomerular filtration rate.
n.c./m/mg, net counts per minute per mg calcium-40.

This investigation has shown that 48 h after the injection of calcium-45 the specific activities of total blood calcium (protein bound plus complexed plus ionic forms) and of its ultrafilterable fraction (complexed plus ionic forms) were dissimilar. Either the filtering membrane handled the two isotopes differently or the various species of blood calcium were labelled heterogeneously. The latter possibly is by far the more likely. Plasma ultrafiltrate is probably identical with glomerular filtrate[11] and its specific activity should be the same as that of the bladder urine if all blood calcium fractions are labelled homogeneously. The investigation has also demonstrated that, at the same 48-h interval, the specific activity of the filtered calcium (complexed plus ionic forms) was greater than that of the excreted calcium (complexed plus ionic forms). The most reasonable explanation of this is that, under the conditions of this study, complexed and ionic forms of calcium have different specific activities and are handled differently by the renal tubule. The calcium-45 appears to label ionic and protein-bound calcium preferentially and complexed calcium only secondarily. Therefore, if the renal tubule selectively re-absorbs ionic calcium, the present results can be explained. In the fifth column of Table 3 the specific activity values are calculated for the calcium re-absorbed. At all times, re-absorbed calcium had a specific activity about 2 per cent greater than did filtered calcium. Since most filtered calcium is reabsorbed, the difference between the specific activities of these two fractions need only be slight to account for a large difference between specific activities of filtered and excreted calcium. This entire explanation is in agreement with present-day physiological concepts concerning renal handling of calcium[10,12,13] and with the data referred to in the introduction[1,2].

A FLUX-CARRIER HYPOTHESIS OF DRUG ACTION

By DR. D. MACKAY

Department of Pharmacology, School of Medicine, University of Leeds

SEVERAL general theories of drug action have been proposed, most of them based on the concept of drug receptors. It has been assumed that when a tissue is exposed to a drug the receptors in the tissue react with the drug to form drug-receptor complexes. The ensuing reaction produces a physiological or biochemical response, often by some unspecified mechanism. The original receptor theory of Clark[1] was modified by Ariens[2] and afterwards by Stephenson[3] to account for the existence of partial agonists. Those modifications apply only to the steady state and assume that the response is related to the number of drug-receptor complexes. More recently, Paton[4] has proposed a 'rate' theory of drug action according to which the response is related not to the number of drug-receptor complexes but to their rate of formation.

The actions of drugs on the neuromuscular junction and on ganglia appear to be too complex to be easily explained by a 'steady state' receptor theory. Compounds which act by blocking transmission across these synapses can be divided into two main classes. The first class is composed of drugs which produce an initial response by depolarizing the membrane of the effector cell. If the drug and tissue remain in contact the initial depolarization may disappear, the post-synaptic membrane repolarizing. However, transmission across the synapse may still be reduced or blocked, this residual block being of the competitive type. Such drugs are said to have a 'dual' type of action[5,6]. Members of the second class of drugs do not produce an initial depolarization and so there is no response by the effector cell. The block which they produce is of the 'competitive' type.

It appeared to me that the competitive type of block could be adequately explained by the receptor theory of Clark[1]. The initial depolarization and subsequent repolarization of the post-synaptic membrane, on the other hand, could be explained by the 'potential' theory of Straub[7] (see also Clark[1]). A complete explanation of the mechanism of action of agents which block synaptic transmission at ganglia and at the neuromuscular junction should therefore contain some of the features of both theories. The flux-carrier hypothesis is an attempt to achieve such a combination.

It is first assumed that the net influx of a drug across a cell membrane may cause the membrane to depolarize. A second assumption is that the flux of drug may be facilitated by mobile carriers or by highly specific fixed sites in the membrane (for example, Wilbrandt and Rosenberg[8], Bowyer and Widdas[9], and Fatt[17]). The possible consequences of these assumptions will now be explored.

There are two main possibilities depending on whether or not the drug, or its carrier complex, can penetrate through the post-synaptic membrane. These possibilities are indicated in Fig. 1*a* and 1*b* respectively. When the drug, *A*, can penetrate the membrane it may act as an agonist, according to the first assumption of the hypothesis. Since it is not known whether carriers are mobile or fixed the results to be expected will be treated qualitatively. The symbol *S* will be used for the site or carrier with which the drug A reacts, and SA represents the drug-carrier complex. The reaction may be written as:

$$S + A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} SA \qquad (1)$$

The sites or carriers will have a certain affinity for the drug, characterized by the affinity constant:

$$K_A = \frac{k_1}{k_2} = \frac{(SA)}{(S)(A)} \qquad (2)$$

The parentheses indicate concentrations of the enclosed molecular species. However, on such a submicroscopic scale concentrations probably have little meaning, and should perhaps be regarded as representing probabilities. The constant K_A might also be considered to represent the distribution coefficient of the drug between the aqueous phases and the membrane surfaces. The net influx, J, of the drug from α to β is given by an equation of the form:

$$J = \frac{D_A}{\delta}\left\{(SA)_\alpha - (SA)_\beta\right\} \qquad (3)$$

if A diffuses in some uncharged form. D_A is the diffusion coefficient of the molecular form in which A penetrates the membrane, and δ is the membrane thickness. The subscripts α and β indicate the positions at which the various concentrations apply. Provided that the diffusion process within the membrane is not too rapid, the equilibrium distribution of the drug between the aqueous phases and the membrane surfaces will be approximately maintained. Equation 2 may then be substituted into equation 3. The net flux through the membrane will then be a function of D_A, K_A, $(A)_\alpha$ and $(A)_\beta$, given by:

$$J = \frac{D_A K_A S_T}{\delta}\left\{\frac{(A)_\alpha}{1 + K_A(A)_\alpha} - \frac{(A)_\beta}{1 + K_A(A)_\beta}\right\} \qquad (4)$$

where:

$$S_T = (S)_\alpha + (SA)_\alpha = (S)_\beta + (SA)_\beta \qquad (5)$$

The initial flux, when $(A)_\beta$ is zero, is:

$$J = \frac{D_A(SA)_\alpha}{\delta} = \frac{D_A S_T}{\delta}\left\{\frac{K_A(A)_\alpha}{1 + K_A(A)_\alpha}\right\} \qquad (6)$$

The maximum initial flux of the drug, obtainable at very high values of $(A)_\alpha$, is then:

$$J_{\max} = \frac{D_A S_T}{\delta} \qquad (7)$$

Since the response is assumed to be related to the flux, it follows that each member of a group of drugs, all of which utilize the same carrier, may produce a different maximal response depending on its D_A value. The diffusion coefficient D_A of a drug may therefore be closely related to its 'intrinsic activity', as defined by Ariens[2].

The initial flux, after a short period of time required for the attainment of a steady state within the membrane, is given by equation (6). As the drug accumulates within the cell the net influx decreases (see equation (5)), until, according to the oversimplified model considered here, it becomes zero when $(A)_\beta$ is equal to $(A)_\alpha$. However, in practice the intracellular and extracellular concentrations of drug may differ even when a new steady state has been attained, because of active processes occurring within the cell.

The rapid initial influx of drug is postulated to cause depolarization of the post-synaptic membrane and thereby produce a response. As the net influx of drug decreases with time the cell will ultimately be able to repolarize the membrane, even though the drug is still present in the intracellular and extracellular fluids. The normal processes involved in the maintenance of the membrane potential of the cell are considered to be in opposition to the effects of the net influx of drug, the influx being a function of time. The drug can be washed out of the extracellular fluid more rapidly than it can be removed from the interior of the cell. If the extracellular fluid is freed of drug in this way and a second dose of drug is then administered, equal to the first, the second response may be less than that obtained initially. This is because the maximum influx during the second dose is less than that during the first, due to accumulation of drug within the cell. The reduced influx results in a reduced response to the second dose. This may be the explanation of tachyphylaxis. Similar ideas have already been proposed by Taylor[10,11]. Previously the idea that entry of depolarizers into cells might be associated with their depolarizing properties was suggested by Burns and Paton[12]. This idea has now been abandoned by Paton[13].

It should also be mentioned that if the drug penetrates the membrane as a cation then the membrane potential may initially be a more powerful driving force than the trans-membrane concentration gradient. If the flux arising from the concentration gradient within the membrane is small compared with that due to the potential gradient, then the initial influx of drug can be shown to be approximately:

$$J = \left[-\frac{Z_A F\,\Delta\varphi}{RT\delta}\right] D_A(SA)_\alpha \qquad (8)$$

$$= \left[\frac{-Z_A F\,\Delta\varphi}{RT\delta}\right] D_A S_T\left[\frac{K_A(A)_\alpha}{1 + K_A(A)_\alpha}\right] \qquad (9)$$

$[-\Delta\varphi]$ is the membrane potential, F the Faraday and Z_A the charge on the species diffusing within the membrane, R is the gas constant and T the absolute temperature. Equation (9) is similar in form to equation (6). In both cases it is assumed that reactions at the membrane surfaces are not rate controlling.

When the drug is unable to penetrate the post-synaptic membrane the situation corresponds to that in Fig. 1b. Since there is no influx of drug there is no depolarization of the membrane. However, the drug I is able to combine with carrier sites at the surface of the membrane. When agonist A and inhibitor I are present together they will compete for carrier. The concentration of carrier-agonist complexes at position α will then be reduced to:

$$(SA)_\alpha = \frac{K_A(A)_\alpha . S_T}{1 + K_A(A)_\alpha + K_I(I)_\alpha} \qquad (10)$$

where K_I is the equilibrium constant for the formation of carrier-inhibitor complex and:

$$S_T = (S)_\alpha + (SA)_\alpha + (SI)_\alpha$$

Substitution of equation (10) into equations (6) and (8) gives the initial flux of agonist in the presence of inhibitor, under concentration or potential gradients. These reduced fluxes are respectively:

$$J = \frac{D_A S_T}{\delta}\left[\frac{K_A(A)_\alpha}{1 + K_A(A)_\alpha + K_I(I)_\alpha}\right] \qquad (11)$$

and:

$$J = \left[\frac{Z_A F}{RT}\ \frac{\Delta\varphi}{\delta}\right] D_A S_T\left[\frac{K_A(A)_\alpha}{1 + K_A(A)_\alpha + K_I(I)_\alpha}\right] \qquad (12)$$

The reduced fluxes would be expected to produce smaller responses. It will be seen that equations (6) and (9), and equations (11) and (12), are closely related to equations (3) and (7) in the paper by Ariens[2].

On the other hand, suppose that an agonist A_1 is added to the extracellular fluid and left in contact with the tissue until the net flux across the membrane has fallen to such a value that the membrane potential has been re-established. If a second agonist A_2 is now added this drug too may penetrate the membrane and cause depolarization. However, in order to do so it must compete with the first agonist A_1 for carrier molecules or fixed sites. The influx of A_2 will therefore be less in the presence of A_1 than it would be in its absence. Thus the agonist A_1 has residual competitive properties even when its depolarizing effect has disappeared.

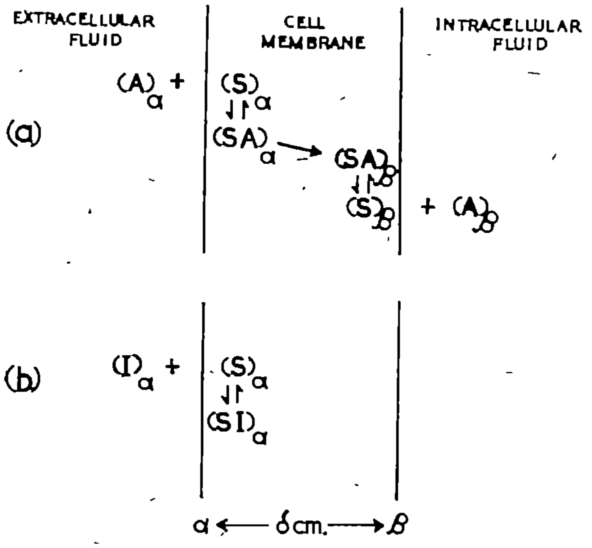

Fig. 1

If A_1 is considered to represent an artificial depolarizing agent, A_2 to represent acetylcholine, either injected or released by stimulation of pre-synaptic nerves, and I to represent 'competitive' blocking agents then consideration of the previous examples will show that the flux-carrier hypothesis is capable of explaining the existence of tachyphylaxis, partial agonists, 'competitive' and 'dual' block at synapses, as well as drug specificity.

The penetration of the post-synaptic membrane by depolarizers might explain the function of the cholinesterase which is present within the effector cell[14] since destruction of acetylcholine penetrating the membrane will reduce the tendency for tachyphylaxis to develop on repeated stimulation of the pre-synaptic nerve.

The suggestion that depolarizers, including acetylcholine, may depolarize the post-synaptic membrane by penetrating it, is contrary to the commonly held belief that acetylcholine acts on the membrane surface. However, this is not the first time that such a possibility has been considered[10,11,12]. The poor intestinal absorption of quaternary nitrogen bases tends to weigh heavily against a ready acceptance of such an idea. However, it should be remembered that synapses are highly specialized structures, and that many polar or charged molecules do in fact penetrate into cells. There is also a limited amount of experimental evidence suggesting that some quaternary nitrogen bases may penetrate cell membranes. Waser[15] has investigated the distribution of curarine, decamethonium and muscarone (labelled with carbon-14) in mouse diaphragm. Whereas with the competitive blocking agent curarine there was a clear-cut localization of the drug on the neuromuscular junction, the depolarizing agents produced more diffuse patterns. Waser states that the latter compounds may be penetrating the cells. A second paper of interest in this connexion is that of Creese, Taylor and Tilton[16], in which they showed that a 'dual'-type quaternary blocking agent, labelled with iodine-131, was concentrated in various tissues. This concentrative uptake of labelled drug was reduced by curarine, a result readily understandable on the basis of the flux-carrier hypothesis.

Several other problems have been deliberately avoided for the present. For example, the depolarization produced by the influx of drug may either be a graded or an all-or-none effect. This also applies to the relation between depolarization and response. There is also the problem of how the influx of a drug could depolarize the membrane. One interesting possibility, suggested by Fatt[17], is that a net influx of base may constitute a net influx of positive charge sufficient to cause depolarization of a small region of the post-synaptic membrane. The local depolarization produced by this flux, which must presumably exceed some critical value, might then act as a trigger to depolarize the membrane of the effector cell.

Although the flux-carrier hypothesis has been designed primarily to explain the actions of drugs on ganglia and on the neuromuscular junction, it may be of wider application. The actions of agents which block synaptic transmission are sufficiently well explained by the hypothesis for it to merit further examination.

I thank Dr. E. R. Clark, Mr. B. Collier, Dr. K. A. Exley and Prof. D. R. Wood and other members of this Department for useful discussions.

GLOMERULONEPHRITIS INDUCED IN MONKEYS BY INJECTIONS OF HETEROLOGOUS GLOMERULAR BASEMENT MEMBRANE AND FREUND'S ADJUVANT

By Dr. R. W. STEBLAY

Department of Obstetrics and Gynecology, University of Chicago

I HAVE previously demonstrated that sheep injected every two weeks with heterologous glomerular basement membrane and Freund's adjuvant uniformly develop fatal, fulminating glomerulonephritis within 27–90 days after the first injection[1]. This new, previously unknown nephritis in sheep presumably occurred by an auto-immune mechanism.

I was interested in applying this experimental technique to other species to test the applicability of this method and to utilize any advantages that study of other species may possess. I was particularly interested in testing this experimental model in monkeys because of their close phylogenetic relationship to man.

This article presents evidence for the successful production of a chronic glomerulonephritis in monkeys by injections of heterologous glomerular basement membrane and Freund's adjuvant.

Glomerular basement membrane (GBM) was prepared from the isolated glomeruli of normal human, rabbit, rat and dog kidneys by a method previously described by me[2].

Table 1. Course of Nephritis induced in Monkeys by Injections of Heterologous Glomerular Basement Membrane (GBM) and Freund's Adjuvant

No. of monkey	Antigen	No. of injections*	Total amount of basement membrane (mg)	Interval during which proteinuria started (days)	Day of killing	Blood urea nitrogen (BUN) at death (mg%)	Renal histology
936	Rat GBM	24	1,200	78–87 (trace)	485	20	Mild diffuse proliferative glomerulonephritis
940	Rabbit GBM	24	1,200	21–32	485	17	Mild diffuse proliferative glomerulonephritis
937	Human GBM	5	250	22–36	102	99 (19 on day 61)	Chronic exudative and proliferative glomerulonephritis
956	Human GBM	3	150	21–32	45 (moribund)	455	ditto
938	Dog GBM	18	900	21–32	313	116 (48 on day 44)	ditto
5	Freund's adjuvant only	20	0	none	330	Normal	Normal limits
994	ditto	16	0	none	240	Normal	Normal limits

* The monkeys were injected with 2 c.c. of emulsion containing 50 mg GBM (wet weight) by multiple portals every 2 weeks. Injections stopped on day 30 because of severe ulcerations at injection sites and were resumed 56 days later.

The GBM was homogenized in isotonic saline with a sonic oscillator (Raytheon sonic oscillator, model *S*102*A*, 50 W, 9 kc, Raytheon Co., Waltham, Massachusetts) for 3–5 mm and made up to a concentration of 38–50 mg (wet weight) per ml. Merthiolate was added to give a final concentration of 1 : 10,000. The homogenized suspension was slowly added to Freund's complete adjuvant (85 ml. 'Bayol *F*', 15 ml. 'Arlacel *A*' and 200 mg *Mycobacterium butyricum* (Difco) to make a 1 : 1 water-in-oil emulsion. The final concentration of GBM in the emulsion varied from 19 to 25 mg/ml.

Seven rhesus (*Macaca mulatta*) monkeys were obtained from a local monkey colony. The monkeys were free of overt disease and had normal urine and blood urea nitrogen. There were 1 male and 6 female monkeys and they ranged in weight from 5 to 10 lb. Each monkey was housed in a separate metabolism cage and fed 'Purina' monkey chow (Purina-Ralston Co., St. Louis, Missouri).

Five monkeys were injected every 2 weeks with 2 ml. of emulsion containing 38–50 mg of GBM. Each monkey received GBM from a single species. The injections were given by intramuscular, subcutaneous and intradermal routes at each administration. For example, 2 ml. of emulsion was divided as follows: 1 ml. intramuscularly, 0·8 ml. subcutaneously in 2 locations, and 0·1 ml. intradermally. Two monkeys were injected with Freund's adjuvant alone as controls. Injections in the 5 monkeys given heterologous GBM were stopped after the 30th day for an interval of 56 days because of ulceration at the injection sites. Periodic urinalyses and blood urea nitrogen determinations were performed on all the monkeys during the course of immunization. The urine protein was determined by the heat and acetic acid method. Blood urea nitrogen, serum albumin, globulin and cholesterol were determined prior to injection and at death in most of the monkeys. Several serial wedge biopsies were taken by surgical exposure of the kidneys on all the monkeys.

The monkeys were killed when judged to have severe nephritis or at termination of the experiment.

At death complete autopsies were performed, bladder urine analysed and the kidneys examined grossly and microscopically. The tissues were fixed in ice cold 10 per cent formalin and stained with hæmatoxylin and eosin, periodic acid–Schiff reagent with Alcian blue and Masson's trichrome stain.

All monkeys injected with heterologous GBM and Freund's adjuvant developed some degree of renal damage as demonstrated by two or more of the following three criteria: proteinuria, azotæmia and glomerular lesions in the kidney. However, the clinical course and histopathology of the nephritis varied considerably in the different monkeys. Because of the small number of monkeys used, it was not possible to ascertain the experimental variables which were responsible for the variations in disease produced. Two monkeys given 16 injections of Freund's adjuvant alone did not develop any evidence of disease at 240 and 330 days. The experimental results are summarized in Table 1.

Proteinuria. The onset of proteinuria is the end of the latent period or incubation period. Proteinuria began between 21–36 days after the first injection for 4 monkeys. This proteinuria was persistent during the entire period of observation and varied between one to four plus. Two monkeys, No. 994 and monkey No. 5, were injected with Freund's adjuvant alone as controls and did not develop proteinuria or nitrogen retention during the entire experimental period of 240 and 330 days for each monkey.

Course of the disease. The 5 treated monkeys may be conveniently divided into 2 groups clinically on the basis of their blood urea nitrogen. Two monkeys, No. 936 and No. 940, had a normal BUN throughout the period of observation and when killed 485 days after the first injection. They had persistent but scant proteinuria during this entire period. They did not appear sick.

On the other hand, the other 3 monkeys all developed azotæmia. They did so at different rates of speed. Monkey No. 956 had a BUN of 455 mg per cent on day 45. This monkey appeared feeble, subdued and anorexic for several days and was killed when in a moribund state. The disease in this monkey was a fatal, fulminating glomerulonephritis. Monkey No. 937 developed azotæmia between 61 and 102 days after the first injection. The BUN was 99 mg per cent at death. This monkey had a more slowly progressing disease. Monkey No. 938 had a BUN of 48 mg per cent on day 44, 113 mg per cent on day 198 and 116 mg per cent when killed on day 313. The course of disease in this animal was relatively stabilized and chronic. He looked thin and listless for 12 weeks before death and developed œdema of hands and feet several days prior to being killed. The total serum protein was 4·8 gm per cent and the cholesterol was 115 mg per cent at time of death. He had moderate serous drainage from ulcerated injection sites for several months. The œdema was felt to be due to hypoproteinæmia secondary to protein loss from the ulcers and in the urine. None of the other monkeys was œdematous in life or at autopsy.

Histopathology. The renal histological changes could be nicely correlated for the 2 clinical groups.

The two monkeys without azotæmia had a homogeneous histological picture. The renal architecture was relatively well preserved. There were casts present in the lumen of some tubules, but the tubule cells were normal. The pathological changes appeared to be confined to the glomeruli. The glomeruli were enlarged and lobulation was increased. Lobular stalk thickening was present and due to hypercellularity probably arising from endothelial (or mesangial cell) proliferation. The endothelial nuclei were small, dark and mature. At least one lobule of almost every glomerulus seemed involved, but there was considerable variation within a glomerulus. In monkey No. 940 there seemed to be increased eosinophilic material in some lobular stalks which might represent early hyalinization. This monkey also had occasional adhesions and focal thickening of the glomerular basement membrane. These 2 monkeys had a mild diffuse proliferative glomerulonephritis.

On the other hand, the 3 monkeys with azotæmia presented a different homogeneous group. In all 3 monkeys the cortical architecture was destroyed. No glomerulus appeared to be completely normal. Some glomeruli were severely distorted due to advanced disease. Lobular stalk thickening was common due to endothelial cell proliferation and hyalinization. The histological variations within this group correlated well with the clinical course. Monkey No. 956 had severe glomerular damage. The glomeruli were partially hyalinized and contained adhesions and occasional fresh cellular crescents. Some glomerular tufts contained areas of necrosis, infiltrates of polymorphonuclear cells and seemed to be occasionally lined with large epithelial cells of varying sizes and shape and which sometimes were found free in Bowman's space. Occasionally a multi-nucleated cell was found fused with a glomerular tuft or free in Bowman's space. Polymorphonuclear and red cells and casts were frequently present in tubules. Marked dilation but little atrophy of the tubules was seen. There was some interstitial fibrosis and interstitial infiltrates of mononuclear cells. Like the clinical course, the histopathological picture was that of a rapidly fulminating injury with signs of acute and chronic damage.

The second and third monkey had much less evidence of acute damage. The glomeruli in monkey No. 938 were severely diseased. They showed endothelial proliferation and marked hyalinization (or scarring) of the glomeruli. There were adhesions present in many glomeruli and occasional old crescents. The histological appearance was compatible with a long-standing process. There was moderate interstitial fibrosis with scant mononuclear cell infiltration. These interstitial cells had small dark nuclei. There was marked dilation and atrophy of tubules with cast formation. The microscopic characteristics of the kidney of monkey No. 937 were intermediate between the last two. Many glomeruli were hypercellular. Lobular stalks were thickened by endothelial cell proliferation and hyalinization. Some glomeruli contained eosinophilic-staining material which sometimes seemed to be in glomerular tufts and sometimes in Bowman's space. Large epithelial cells lined the glomerular tufts or were free in Bowman's space. An occasional multinucleated cell was seen in Bowman's space. A frequent distinctive lesion was a peculiar fusion of loosely proliferating spindle-shaped cells between part of a glomerulus and the pericapsular connective tissue. This loose proliferation of cells seemed to obliterate Bowman's capsule at the place of fusion. Some tubules contained hyaline droplets and some tubular lumens contained red cells. There was less interstitial fibrosis than in monkey No. 938 and more interstitial cell infiltration. Sometimes these cells with small dark nuclei seemed to be invading tubules. These 3 monkeys with azotæmia may be said to have severe chronic mixed exudative and proliferative glomerulonephritis.

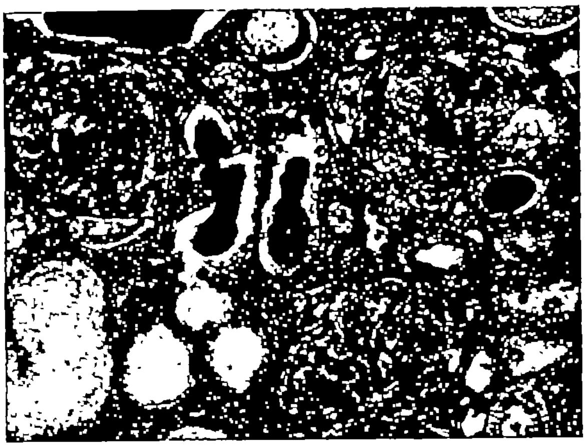

Fig. 1. Kidney section taken from monkey No. 956, 45 days after the first of 5 injections of a total of 250 mg of human GBM. The BUN was 455 mg per cent. The glomeruli are severely damaged. They are partially hyalinized and hypercellular. Extensive fibro-epithelial proliferation obliterates Bowman's space. There is wide variation in size and shape of the epithelial cells. Hyaline droplet degeneration is present in proximal tubules. Most tubules are dilated and contain casts. There is some interstitial fibrosis and cellular infiltration. (Periodic acid–Schiff × 170)

Focal areas of interstitial fibrosis, focal areas of inflammatory cells and pericapsular fibrosis were occasionally found in normal monkey kidneys and the control monkey kidneys given Freund's adjuvant alone. No importance therefore was attached to these occasional histological findings. The glomeruli of the monkeys given Freund's adjuvant alone appeared normal.

Skin tests for hypersensitivity. The monkeys were tested for delayed hypersensitivity to the antigens used for immunization. 0·1 ml. homogenized GBM (concentration 10 mg/ml.) was injected intradermally on the abdomen of each monkey. The reactions consisted of a firm swelling which seemed to start about 3–6 h after injection and reached a maximum at 24–48 h. Sometimes a red-brown area could be seen in the centre of the swelling and occasional oozing from this coloured area was observed. Each of the 5 monkeys when injected with the GBM used for immunization of that monkey showed a delayed skin reaction as judged by gross appearance. The two control monkeys did not have a similar swelling at site of injection with any of the GBM antigens.

I have previously observed that sheep injected every 2 weeks with heterologous GBM and Freund's adjuvant regularly and uniformly develop a fatal, fulminating glomerulonephritis within 90 days after the first injection[1]. On the contrary, even with the small number of monkeys used, there is a wide variation in the course of the disease. Two monkeys did not even develop azotæmia 485 days after the first injection. Histologically these 2 monkeys had a mild diffuse proliferative glomerulonephritis that seems to have stabilized as judged by serial biopsies.

Even the 3 monkeys which became azotæmic had somewhat different clinical and histological courses although they could be readily grouped together as distinctive from the non-azotæmic pair of monkeys. Monkey No. 956 had a fatal fulminating course clinically. This monkey was moribund on day 45. Its kidney revealed severe acute and chronic glomerular damage. The changes in the tubules and interstitial tissue were secondary to the glomerular changes and had not had time to develop far advanced chronic stigmata. Monkey No. 937 had more advanced interstitial fibrosis and tubular changes with less evidence of acute changes. Monkey No. 938 had relatively stabilized elevated azotæmia for about 9 months. Its kidney revealed the most advanced interstitial fibrosis and long-standing tubular changes. The glomeruli appeared to have progressively hyalinized. These 3 monkeys may be said to have severe chronic mixed exudative and proliferative glomerulonephritis. An unusual feature of this monkey nephritis was the occasional presence of multi-nucleated giant cells in Bowman's space.

The histological variations might be a function of the kidney antigen of the species injected. Since one monkey was used for each antigen (two in the case of human GBM), nothing can be said about whether this variation was due to the antigen used or was a random distribution among the monkeys to essentially the same kind of stimulus (Table 1).

It may be that the histological features of the kidney damage are more characteristic of the species injected. The histological appearance of the nephritis in the sheep seemed quite different from that induced in the monkeys. Further, the rat lesion described in the auto-immune rat nephrosis by Heymann[3] is said to be a membranous glomerulonephritis and is different from either the sheep or monkey lesions.

In conclusion, the injection of heterologous GBM and Freund's complete adjuvant into 5 monkeys produced glomerulonephritis as judged by renal histology and proteinuria in two monkeys; in addition, azotæmia was present in the three other monkeys. The glomerular lesion presumably occurs by an auto-immune mechanism. The 2 monkeys without azotæmia had similar mild diffuse proliferative glomerulonephritis histologically and a similar clinical course. The 3 monkeys with azotæmia had severe diffuse glomerular disease and may be said to have chronic mixed exudative and proliferative glomerulonephritis.

All 5 monkeys demonstrated delayed hypersensitivity to the antigens used for injection as judged by the gross appearance of the swellings which resulted from intradermal injections of the antigen.

The two control monkeys injected with Freund's adjuvant alone had normal urine and kidneys. They did not have delayed skin reactions to GBM antigens.

This work was supported in part by grant *H*-4785 from the National Institutes of Health, the Chicago Heart Association, and the Schering Corporation. I thank Dr. M. Edward Davis and Dr. Mark Lepper for their advice and Dr. Robert Jennings for aid in interpreting the histopathology.

EFFECT OF HYPERTONIC SALINE INJECTIONS ON THE SECRETION OF THYROID HORMONES IN RABBITS AND GUINEA PIGS

By G. FEUER *

Department of Biochemistry, Institute of Psychiatry, University of London

THERE have been some contradictory observations about whether the activity of the thyroid gland is affected directly by administration of vasopressin or whether vasopressin acts indirectly by increasing the plasma thyrotropic hormonal level. Several authors observed a change in thyroid function in experimental animals and also in human beings following the injection of antidiuretic hormone[1-5]; others did not find any such change[6,7]. Recently, Garcia *et al.*[8] found that vasopressin exerted a direct action on the excretion of thyroid hormones.

Verney[9] has shown that the urine volume is controlled by a mechanism sensitive to changes in the osmotic pressure of the blood. If during water diuresis in normal animals a hypertonic solution of salt, dextrose or sucrose was injected into the carotid artery, or intravenously, antidiuretic hormone was released and a prompt diminution in the rate of water excretion was seen. Using his technique this work is an attempt to elucidate further the question of whether the appropriate stimulation of the discharge of endogenous vasopressin is associated with an alteration of thyroid function.

Female chinchilla rabbits, body-weight 2–3·5 kg, were injected subcutaneously with 100 μc. carrier-free iodine-131. After two days, when nearly all the inorganic iodine has been excreted and only iodine-131-labelled thyroid hormones were present in the gland and in the circulation, the secretion of endogenous thyrotropic hormone was blocked by subcutaneous injection of 60 μg thyroxine. The thyroxine injection was repeated every day for a week at the end of each day's experiments.

The rabbits were conscious and unrestrained throughout the whole experiment; between 9 a.m. and 5 p.m. the food and water consumption were restricted. The injections of salt solutions were carried out either subcutaneously or intravenously. 10–50 ml. 0·9, 0·6 and 10 per cent solutions were administered within 10–20 min in 10-ml. portions, or infused over a period of 2 h. During infusion the animals were placed on a hot plate at a temperature of 27°–30° C. The left marginal ear vein was cannulated to obtain blood samples, and the solutions were infused into the right marginal ear vein.

Every 2 h blood samples were taken; about 2 ml. were collected into tubes containing 2–3 drops of heparin and the radioactivity of 1·0 ml. blood was determined.

Fig. 1 shows a representative experiment. It is seen from this figure that the iodine-131 hormones decayed in the rabbits' blood throughout the whole experiment. The only increase in the radioactive hormone-level was observed when 50 ml. of 10 per cent sodium chloride was infused; the injection of 50 ml. 0·9 or 0·6 per cent sodium chloride had no effect as did the placing of the animal on the hot plate. The increase of radioactivity was proportional to the amount of injected hypertonic saline solution. 40 ml. 10 per cent sodium chloride caused 130 per cent, 20 ml. 75 per cent, 10 ml. 35 per cent increase of the hormonal iodine-131 level of the blood.

The plasma was separated from the blood sample, the protein-bound iodine precipitated and the radioactivity assayed. 82–97 per cent of the radioactivity of the plasma was found in the precipitate. This result showed that the rise of radioactivity in the blood was due to protein bound iodine-131. This response was similar to that observed after direct vasopressin administration[8].

Similar results were obtained with 8 rabbits. Each week groups of 4 rabbits were used and permutation of

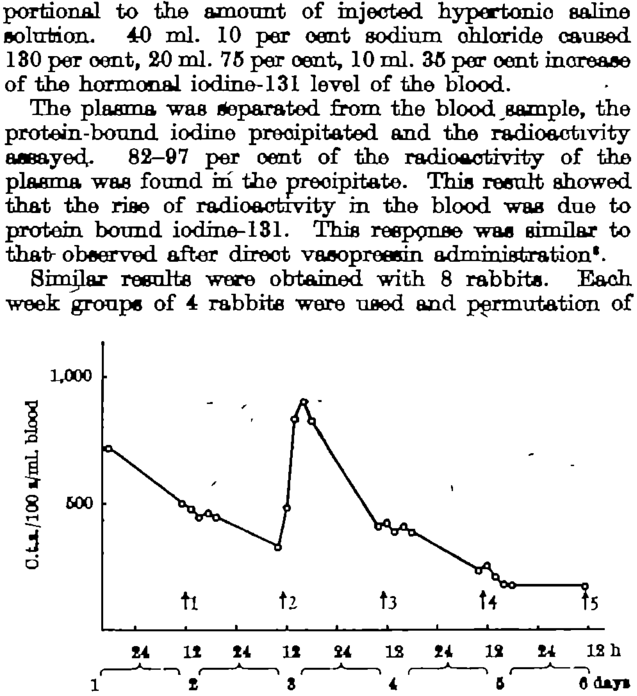

Fig. 1. Effect of different salt solutions and water deprivation on the release of thyroid hormones in the rabbit The curve represents the blood-level of iodine-131 thyroid hormones (c.t.s./100 s/ml. blood) during the 6 days experiment. Blood samples were taken every 2 h between 9 a.m. and 6 p.m. and counts were taken on an Ekco scintillation counter. At the time marked with arrow 1, 50 ml. 0·9 per cent sodium chloride, at the arrow 2, 50 ml. 10 per cent sodium chloride, and at the arrow 3, 40 ml. 0·6 per cent sodium chloride were injected over a period of 20 min, the animal being placed on a hot plate at 28° C for 2 h; at arrow 4 the rabbit was placed for 2 h on the hot plate. At arrow 5 the animal was killed

infusions with the different solutions during subsequent days was carried out.

* Present address: Medical Research Council, Neuropsychiatric Research Unit, Carshalton, Surrey.

Subcutaneous injection of 5–10 ml. hypertonic sodium chloride solutions caused an increased concentration of labelled thyroid hormones in the blood of female guinea pigs, body-weight 500–700 g. In these cases 60 µc. carrier-free iodine-131 was injected subcutaneously and after two days the pituitary activity was inhibited by 50 µg thyroxine. The blood samples were collected from the ear vein.

The classic work of Verney[9] demonstrated that hypertonic saline solutions exerted an action on the posterior pituitary and stimulated the release of stored vasopressin from the gland. Axelrod *et al.* found that prolonged administration of sodium chloride affected the function and the morphology of the thyroid gland[10–12].

Our experiments give evidence that the acute stimulation of the neural lobe by the administration of hypertonic sodium chloride solution, which resulted in a relative deprivation of water in normal animals, led to a rise in the output of the thyroid hormones into the circulation reaching a maximum between 2–6 h depending on the amount injected. The change in endogenous thyrotropic hormone was blocked by a rather large amount of thyroxine so the increase in thyroid activity was not affected by anterior pituitary activity. Evidently the secretion of antidiuretic hormone seems to be responsible for the activation of the thyroid gland, or it is possible that the liberated vasopressin by the effect of hypertonic saline solution could overcome the thyroxine block of the pituitary and release endogenous thyrotropic hormone. Although these results are not conclusive (some further experiments with anterior and posterior lobectomized animals and study of the effect of hypertonic saline solution on isolated thyroid lobes would be necessary) it is supposed that as well as the anterior pituitary, the posterior lobe also plays some physiological part in the regulation of the thyroid function.

I thank Prof. H. McIlwain for his support during the progress of this work, and the Ford Foundation for financial aid.

ENCEPHALOMYOCARDITIS VIRUS AND ITS RIBONUCLEIC ACID: SEDIMENTATION CHARACTERISTICS

By MEMBERS OF STAFF OF THE VIRUS RESEARCH UNIT
Medical Research Council Laboratories, Carshalton, Surrey

Sedimentation Coefficients of Encephalomyocarditis Virus and its Ribonucleic Acid

INFECTIOUS ribonucleic acid (RNA) has been obtained from several animal viruses or from cells infected with animal viruses[1]. Little is known of the physical properties of this RNA, mainly through difficulty in preparing sufficient quantities of pure material; sedimentation coefficients of infective RNA have been estimated for foot-and-mouth disease and mouse encephalitis viruses[2,3]. This article describes the determination of sedimentation coefficients by a modification of the procedure of Yphantis and Waugh[4] (using a cell with a fixed rather than movable partition) which does not require pure material. The material is centrifuged in a separation cell and the amount left above the partition at the end of the run (*Cu*) is compared with that originally present (*Co*). A specific quantitative test for the material under investigation is needed; infectivity, measured in plaque-forming units, and hæmagglutinating ability, measured in hæmagglutinating units, were both so used to determine the sedimentation coefficient of encephalomyocarditis (EMC) virus; infectivity, measured under different conditions, was also used for a similar determination with EMC virus RNA.

EMC virus was grown *in vitro* in continuously agitated suspensions of Krebs-2 mouse ascites carcinoma cells[5]. When more than 80 per cent of the ascites cells were dead, the cell debris was removed by centrifuging at 3,000*g*/5 min followed by 9,000*g*/15 min. The tissue culture supernatant obtained was not purified further before determination of the sedimentation coefficient of the virus, or extraction of its RNA. The number of hæmagglutinating units and plaque-forming units was determined by the method of Sanders, Huppert and Hoskins[5].

Infective RNA was prepared from the crude virus by phenol extraction in the presence of bentonite[6] as described by Montagnier and Sanders[7]. The precipitated RNA was stored at 4° in 67 per cent ethanol until required for use when it was redissolved in 0·01 M phosphate buffer *p*H 6·8. Infectivity of the RNA was measured by plaque titration[8]; the ability of RNase to destroy infectivity was tested for all RNA preparations.

The sedimentation coefficient of EMC virus was determined, using plaque-forming and hæmagglutinating units as markers at 20° and at speeds of 20,410 and 29,500 r.p.m. in a Spinco model *E* ultracentrifuge. Schlieren optics was used to check the alignment of the centrifuge cell and the level of the meniscus. Several runs were made for different periods of time (10–30 min) to give a range of *Cu*/*Co* values of 1–50 per cent. The results from the virus infectivity (Table 1) give a mean value for the sedimentation coefficient of 161*s* with a standard error of ± 3·3. The sedimentation coefficient from the hæmagglutinin activity was 164*s* with a standard error of ± 4·5; typical results obtained are shown in Table 2. On some occasions the contents of the top compartment of the fixed partition cell were used for measurements of both hæmagglutinating and plaque-forming units and the values for sedimentation coefficients obtained were very similar; compare, for example, samples 364–1, –2 and –3 (Tables 1 and 2).

Table 1. SEDIMENTATION COEFFICIENT OF EMC VIRUS USING INFECTIVITY AS MARKER

Sample	Speed (r.p.m.)	*Cu*/*Co*	S_{20}
325–2	29,500	7·8	154·8
364–1	29,500	12·5	165·1
364–2	29,500	8·9	152·5
364–3	29,500	10·7	176·6
377–1	20,410	24·6	169·7
377–1	20,410	25·0	164·0
377–2	20,410	2·8	158·5
377–3	20,410	2·6	146·4

Mean value S_{20} 161 ± 3·3 (*S.E.* 8 determinations)

Table 2. Sedimentation Coefficient of EMC Virus using Haemagglutinin as a Marker

Sample	Speed (r.p.m.)	Cu/Co	S_{20}
322–1	29,500	3·1	148·5
361–1	20,410	6·3	178·8
361–2	20,410	12·5	176·6
364–1	29,500	12·5	165·1
364–2	29,500	6·3	157·8
364–3	29,500	12·5	172·4
377–3	20,410	1·6	147·8

Mean value S_{20} 163·9 ± 4·5 (*S.E.* 14 paired determinations)

Our value of 161–164*s* for the sedimentation coefficient of virus infectivity and hæmagglutinin is close to that of 156–160*s* quoted by Faulkner, Martin, Sved, Valentine and Work[9] obtained by the sedimentation velocity analysis of crystalline virus. The similarity of the figure shows that the method of determining sedimentation coefficients described in this present report gives results close to that obtained by more conventional methods. Since the S_{20} value obtained for virus hæmagglutinin was almost identical with that of virus infectivity it would appear that both these virus properties reside in the same particle. One of the disadvantages of the present method of determining sedimentation coefficients is that if two or more particles with a common property which is used as a specific marker, but with different S_{20} values, are present, then the value obtained will only be an average sedimentation coefficient, the exact value of which will depend on how much of each component is present. Since a similar figure was obtained for virus infectivity and hæmagglutinin (cf Tables 1 and 2), this suggests that other particles having either of these properties (for example, free hæmagglutinin) in crude virus preparations, must be present in small amounts only, if at all.

Table 3. Sedimentation Coefficient of EMC Virus RNA (Plaque-forming Units) using Infectivity as a Marker

Sample	Speed (r.p.m.)	Cu/Co	S_{20}
363–4	44,770	35·9	38·8
384–1	44,770	4·3	36·2
384–1	44,770	4·8	35·1
384–3	44,770	1·1	36·1
383–1	44,770	1·6	36·4
383–1	44,770	2·1	38·1

Mean S_{20} 37 ± 0·5 (*S.E.* 6 determinations)

Virus RNA was run at a speed of 44,770 r.p.m. for 10–30 min giving values of Cu/Co of 1–40 per cent (Table 3). This gives a mean sedimentation coefficient of 37*s* with a standard error of ± 0·5, which fits in well with the results of Montagnier and Sanders[7]. They mixed virus RNA labelled with phosphorus-32 with RNA from uninfected Krebs cells and centrifuged the mixture on a sucrose gradient; the RNA infectivity and radioactivity was found to sediment faster than the largest cellular RNA component, which has an S_{20} value of about 30*s*. A value of 37*s* was also obtained for the RNA from foot-and-mouth disease virus by Strohmaier and Mussgay[2] using a deuterium oxide–water density gradient.

Values of 31–32*s* have been suggested for RNA from mengo, West Nile encephalitis and poliomyelitis viruses[10] and from eastern equine encephalitis virus[11]. These conclusions are based on the fact that the infectious components present were of high molecular weight and that preparations from infected cells when examined in the analytical ultracentrifuge had no component detectable by optical methods with a sedimentation coefficient greater than 31–32*s*. Similarly, RNA from EMC infected cells does not show any component with an S_{20} value greater than 30*s* when examined in the analytical ultracentrifuge[12] using either schlieren or ultra-violet optics. Since the S_{20} value for EMC virus RNA appears to be about 37*s*, this probably means that there is so little virus RNA present in infected cells that it cannot be detected in the analytical ultracentrifuge using conventional methods. Moreover, analysis by sucrose gradient centrifugation[7] shows that the bulk of the infectious RNA recoverable from infected cells, as detected by plating for infectivity, behaves like the RNA extracted from purified virus, for example, sediments appreciably faster than the 30*s* cell component. The values of 31–32*s* for the virus RNA itself from mengo, West Nile, poliomyelitis and EEE viruses are thus open to doubt[10,11]. This is particularly so since evidence that poliomyelitis virus RNA is larger than cellular RNA is suggested by the work of Kubinski and Koch[13], who showed viral RNA was eluted after cellular RNA when RNA from infected cells was chromatographed on a methylated serum albumin–'Celite' column; this system is thought to separate nucleic acids according to chain-length[14], and also by that of Fenwick[15], who found that the newly labelled RNA in poliomyelitis virus-infected cells sedimented slightly faster than the heaviest cell RNA and at the same rate as RNA from pure virus.

Gierer[16] has shown that the molecular weight (M) and sedimentation coefficient of TMV RNA may be equated as follows:

$$M = 1100\, S^{2\cdot 2}$$

If it is assumed that the RNA from EMC virus has similar physical properties to TMV RNA, then an S_{20} value of 37*s* would give a molecular weight for EMC virus RNA of $3\cdot 1 \times 10^6$. EMC virus contains 30 per cent RNA and an S_{20} value of 160*s* for the virus would give a particle of a molecular weight of about 1×10^7 (ref. 9). This would mean the RNA present in the virus particle would have a molecular weight of the order of 3×10^6. Since this agrees with the figure obtained from the S_{20} value of EMC RNA it suggests that there is one RNA molecule of molecular weight—3×10^6 per EMC virus particle and that this can be extracted as a single piece with phenol.

We thank R. Hay and G. Warriner for assistance.

Sedimentation Properties of Infective Ribonucleic Acid extracted from Encephalomyocarditis Virus

EMC virus itself, and Krebs-2 cells infected *in vitro* with this virus, yield infective ribonucleic acid (RNA) when extracted with phenol[1,2]. Before the precise mode of replication of viral RNA can be investigated, answers must be obtained to the following questions: Is the whole RNA content of one virus particle required to carry the genetic information for virus replication: that is, does the size of the smallest infective unit of RNA correspond to the RNA content of a single virus particle? Infective RNA, in general, has only a fraction of the infectivity of the virus from which it can be extracted[3,4]. Is this due to the relative insensitivity of the system used to assay RNA infectivity, or does the infectivity recorded belong only to a small fraction of the extracted molecules, most of them having been broken up by the extraction method ?

To answer either of these questions requires knowledge of the physical properties of EMC virus RNA; until now it has been impossible to examine these directly, mainly owing to the technical difficulty of obtaining sufficient quantities of pure material. However, we have now been able to obtain tentative answers to the above questions by studying the sedimentation behaviour of a small quantity of EMC viral RNA labelled with phosphorus-32 in a sucrose gradient, assaying both radioactivity and RNA infectivity, and using non-radioactive Krebs-2 cell RNA with known sedimentation values as a velocity marker. At the end of centrifugation, fractions were collected and analysed for three properties: (1) radioactivity; and (2) infectivity, indicating the position of viral RNA; (3) ultra-violet absorbance at 260 mμ locating the cellular RNA. Knowing the sedimentation coefficients of the cellular RNA components, an approximate value could be assigned to the viral RNA. Moreover, a comparison of the respective positions of the radioactive and infective bands would indicate whether the majority of infective molecules differ in size from the bulk of the molecules extracted by the procedure used.

EMC virus, having its RNA heavily labelled with phosphorus-32, was obtained by growing the virus *in vitro* in continuously agitated suspensions of washed Krebs-2 ascites cells (37° C; multiplicity of infection × 3). The medium consisted of Earle's saline buffered with citrate instead of phosphate and containing 100 μc. of carrier-free phosphorus-32 per 10^7 cells. The label was added 1 h before infection. At 5 h after infection, a time at which all infective RNA had been synthesized in the cells[5], the culture was diluted with fresh medium containing the normal concentration of unlabelled phosphate, and incubation continued until 16–18 h after infection. Labelled virus in the supernatant was purified by the method of Faulkner *et al.*[6], using trypsination, chromatography on two successive calcium phosphate (brushite) columns and centrifugation. Virus eluted from the first column was treated with 1 per cent sodium deoxycholate in order to lyse cellular endoplasmic membranes, which electron microscopy showed occasionally to contaminate virus preparations when this step was omitted. To identify the radioactive final product as a single viral component, a portion was centrifuged to equilibrium in a solution of rubidium chloride with an initial density of 1·33 using the method described by Crawford[7]. After equilibrium had been reached (40 h; 34,000 r.p.m.; *SW* 39 head) analysis of fractions collected from the centrifuge tube showed that both radioactivity and virus hæmagglutinating ability banded together in a single peak at a density of 1·33 characteristic of EMC virus.

RNA was extracted from such virus preparations in acetate buffer 0·01 M, ethylenediamine tetraacetic acid (EDTA) 0·025 M, *p*H 7, containing 0·05 per cent of bentonite, a powerful absorbent of ribonuclease[8]. Two alternative methods of deproteinization were used: in the first, the virus suspension was shaken twice for 10 min at room temperature by hand with an equal volume of redistilled analytical reagent phenol; in the second method, the virus suspension was shaken with 0·25 per cent sodium dodecylsulphate for 10 min and then 2 or 3 times with the Sevag mixture (chloroform/octanol[9]). The subsequent stages of preparation were identical for both methods. The aqueous layer containing RNA was freed from bentonite by high-speed centrifugation (35,000 r.p.m.; 15 min) and the RNA precipitated by ethanol without addition of a carrier; to absorb the last traces of protein (particularly ribonuclease), the RNA pellet was again dissolved in a suspension of bentonite (0·05 per cent), and the bentonite removed by centrifugation. The final RNA extracted by both methods contains from 60–75 per cent of the radioactivity originally present in the virus preparation; the remainder could be found in the reagents used for extraction. The infectivity of such preparations was remarkably stable (several months at 4° C) provided that the storage medium contained both EDTA and bentonite. Both methods of extraction yielded specific infectivities of about 1 × 10^3 infective units per μg of RNA, as recorded by plating on agar layers of Krebs-2 cells[10]. Krebs-2 cellular RNA was also extracted by the phenol method (using reagents containing bentonite and EDTA as described here.

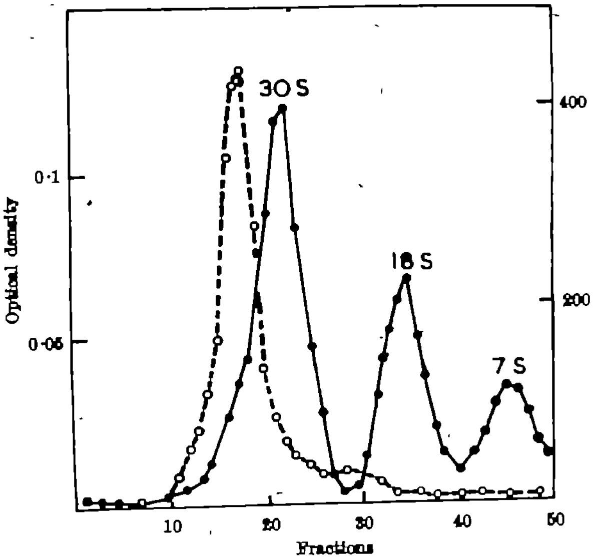

Fig. 1. Sedimentation of a mixture of RNA from Krebs-2 cells and ^{32}P-labelled EMC virus RNA, both extracted by phenol, in a sucrose gradient 10–20 per cent containing *tris*–HCl 0·005 M, EDTA 0·02 M, *p*H 7·2 (25,000 r.p.m., 12 h + 4° C, *SW* 25 rotor). After centrifugation, the tube was pierced and fractions of approximately 0·5 ml. were collected. Fraction No. 1 is the first fraction collected from the bottom of the tube. Continuous line, optical density at 260 mμ; dotted line, radioactivity

By centrifugation in the Spinco model *E* analytical centrifuge, using either schlieren or ultra-violet optics, cellular RNA can be resolved into 3 components having sedimentation values of 30*s*, 18*s* and 5–7*s* at neutral *p*H and moderate ionic strength (sodium phosphate buffer 0·02 M). The same 3 components could be identified when these cellular RNA preparations were centrifuged on a sucrose gradient (Fig. 1). The two rapidly sedimenting components presumably come from ribosomes; the

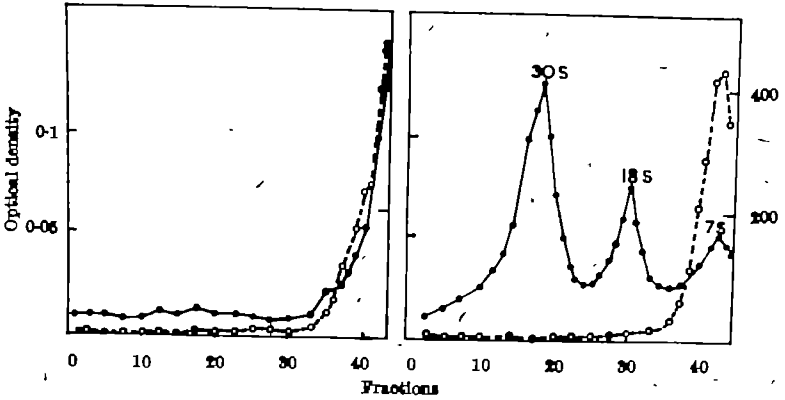

Fig. 3. Effect of ribonuclease. (a) Sedimentation in a sucrose gradient of a mixture of Krebs-2 cellular RNA and ^{32}P-labelled EMC virus RNA, both treated with ribonuclease (1 μg, 30 min, 10° C). Conditions of centrifugation as in Fig. 1. (b) Sedimentation of a mixture of untreated Krebs-2 cellular RNA and ^{32}P-labelled EMC virus RNA, treated with ribonuclease (0·5 μg, 1 h, 10° C), and then freed of enzyme by the addition of 0·1 per cent of bentonite (latter removed by centrifuging 20 min at 36,000 r.p.m.). Medium of centrifugation as in Fig. 1. Run, 18 h. 25,000 r.p.m. Continuous line, optical density at 260 mμ; dotted line, radioactivity

slowest fraction (4–7s) probably includes the 'transfer RNA' fraction which is soluble in 1 M sodium chloride.

When EMC virus RNA labelled with phosphorus-32 is mixed with cellular RNA and centrifuged on a sucrose gradient, the former, as detected by its radioactivity, sediments as a single peak travelling faster than the 30s component of cellular RNA (Fig. 1). When EMC RNA was centrifuged in the absence of marker RNA a similar sedimentation profile was obtained, showing that the sedimentation of viral RNA was not affected by the presence of cellular RNA, provided that the concentration of the latter was not too high ($\leqslant$ 500 μg/ml.) and that it too had been extracted in the presence of a chelating agent. It was also found necessary for EDTA to be present in the sucrose gradient itself in order to sharpen separation between the different components. Control with the analytical centrifuge showed that sodium versenate at the same ionic strength as that used in the gradient did not affect, or only slightly diminished, sedimentation coefficients of the components of cellular RNA.

Viral RNA infectivity, as tested by plating on Krebs-2 cells, sedimented at the same rate as radioactivity (Fig. 2). Comparison between the radioactive curve and the curve for infectivity, however, indicated that there is a tail of lighter radioactive material the specific infectivity of which is too low to be significant. These results indicate quite clearly that the major fraction of the RNA consists of molecules of a given size, an unknown proportion of which is both infective and radioactive, and that only a small part of the RNA is broken by the method of extraction. This portion loses its infectivity but remains radioactive. Similar results were obtained whatever method of extraction of viral RNA was used, and this makes it unlikely that the peak of sedimenting material observed is an artificial product of the method of extraction. There is, moreover, no doubt that the material studied is RNA. All the sedimenting peaks are sensitive to extremely small amounts of ribonuclease (0·5 μg/ml., 1 h at 4° C) which reduces the RNA to small pieces sedimenting at low velocities (Fig. 3).

Evaluation of the molecular weight of infective EMC RNA. Cellular ribosomal RNA consists of two components sedimenting at 18 and 30s respectively, and having molecular weights of 7 × 10^5 and 1·5 × 10^6 (refs. 11 and 12). Assuming that the viral RNA has the same fundamental structure as ribosomal RNA, our results suggest that EMC virus RNA has a molecular weight > 2 × 10^6. This is confirmed by an independent determination of the sedimentation velocity of EMC viral RNA in the Spinco analytical ultracentrifuge. RNA from a large batch of purified virus was sedimented in the analytical centrifuge and its sedimentation examined by ultra-violet optics. The value obtained was 37s, which is in good agreement with data obtained by Burness *et al.* (preceding communication), using an independent method. They found a sedimentation value for EMC RNA of 37s and calculated a molecular weight of 3 × 10^6. On the basis of the analytical results of Faulkner *et al.*[9], this would suggest that the infective RNA molecule extracted from purified EMC virus corresponds to the entire RNA content of a single virus particle. Investigation of the change in ultra-violet absorbance which follows heating suggests that EMC RNA exhibits in solutions of moderate ionic strength a similar degree of intramolecular hydrogen bonding to the cellular RNA components. Moreover, sedimentation values of EMC RNA, like those of both 18s and 30s ribosomal RNA, are strongly dependent on the ionic strength of the medium of centrifugation, and also on the presence of divalent cations. Fig. 4 shows the result of an experiment in which a mixture of EMC virus RNA labelled with phosphorus-32 and Krebs-2 cellular ribosomal RNA was centrifuged at very low ionic strength (0·001 M EDTA). Under these conditions ribosomal RNA molecules show a greater degree of extension than at higher ionic strengths, owing to rupture of intramolecular hydrogen bonds, and consequently have lower sedimentation coefficients[13]. In media of low ionic strength the sedimentation constant of EMC viral RNA is also diminished, but to a much greater degree than that of the cellular component; consequently the radioactive peak in 0·001 M EDTA now lies between the peaks of '30s' and '18s' cellular RNA, and not in front of the former. Such variations, however, are fully reversed by increasing the ionic strength, and infectivity always remains associated with the radioactive viral peak. A reasonable assumption based on such results is that EMC virus RNA in solution, like ribosomal RNA, is a single-stranded chain.

Recently we have also investigated the sedimentation properties of infective RNA synthesized by cells in response to infection. Such an RNA is synthesized before the appearance, within the cells, of mature virus particles.

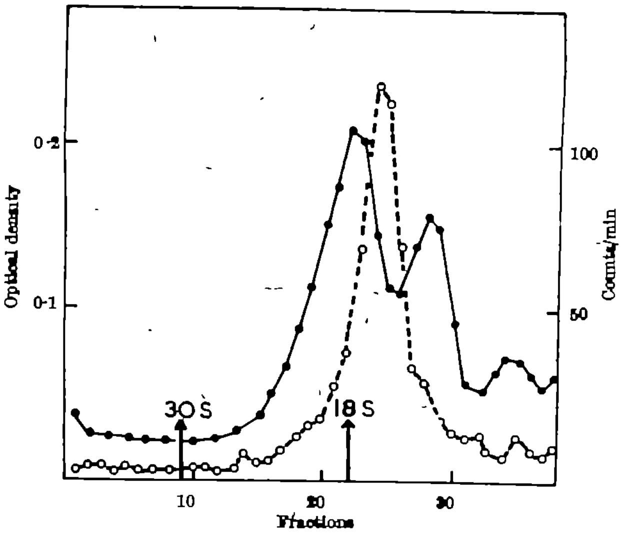

Fig. 4. Sedimentation of a mixture of phenol-extracted Krebs-2 cellular, and ^{32}P-labelled EMC virus RNA, in a sucrose gradient 10–20 per cent containing *tris*–HCl 0·001 M, EDTA 0·001 M, pH 7·2 (25,000 r.p.m., 15 h, 4° C, *SW* 25 rotor)
Continuous line, optical density at 260 mμ; dotted line, radioactivity. The positions occupied by the 18s and 30s components in a high ionic strength medium as in Fig. 1 are indicated by the arrows

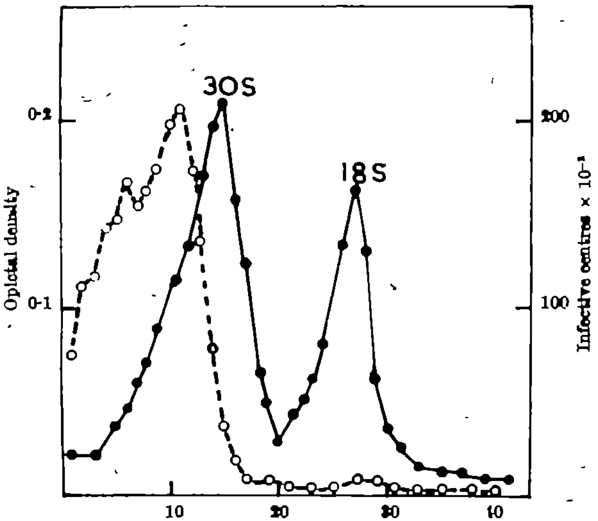

Fig. 5. Sedimentation in a sucrose gradient of RNA extracted by phenol from Krebs-2 cells incubated for 3 h at 37° C after infection by EMC virus at multiplicity 5 (fraction insoluble in 1 M NaCl). Medium of centrifugation as in Fig. 1—14 h, 25,000 r.p.m. Continuous line, optical density at 260 mμ; dotted line, infectivity

Fig. 5 shows the sedimentation of infectivity when RNA extracted from infected cells is spun on a sucrose gradient. The bulk of the infective molecules sediments faster than the 30s ribosomal component but the peak found is broader than when virus RNA is centrifuged as a mixture with cellular RNA. Experiments are in progress to decide the relevance of these differences to the process of RNA replication.

Our results at present, however, provide a clear answer to the two questions proposed at the beginning of this article. When tested by its ability to perform all the duties of a virus particle, that is, to produce a plaque on an agar suspension of susceptible cells, infective RNA appears to consist of molecules each of which corresponds in size to the total RNA content of one virus particle. Phenol extraction of virus releases the bulk of the RNA in the form of molecules of this size. The relative lack of infectivity of RNA preparations compared with the virus from which they have been derived must therefore be ascribed to inefficiencies in the assay system used rather than to breakage of RNA occurring during extraction, although, conceivably, the extraction procedures might inactivate most of the RNA without breaking it, or else break it near one end with a negligible effect on sedimentation rate. However, recent improvements in the assay system have now achieved RNA infectivities of the order of 0·1–1·0 per cent of the infectivity of the purified virus from which these preparations were made, suggesting that it is the sensitivity of assay rather than the quality of the RNA which is at fault.

We thank Mrs. B. Burford and Miss M. Wall for assistance.

SELECTION IN NATURAL POPULATIONS: *MERYCHIPPUS PRIMUS*, A FOSSIL HORSE

By DR. LEIGH VAN VALEN*
Department of Zoology, University College, London

THE distribution of intensities of phenotypic selection in natural populations has never been adequately investigated. There are a rather larger number of instances (to be reviewed elsewhere) in which phenotypic selection in natural populations has been demonstrated and from which estimates of intensity can be made[1]; but most of these serve mainly to show that natural selection does in fact occur. The reason for this is that there is an unknown degree of bias toward high intensity in these cases in that for the most part only significant results are published. Cases in which natural selection is not demonstrated are presumably often left unpublished.

Many groups of organisms are unsuitable for the kind of investigation to be reported here. The two main requirements are that a method of establishing individual relative age at least approximately must be available, and that a character must be available which does not change ontogenetically between these age-groups. The characters to be reported here (and in the press, *Nature*) are chosen without respect to the likelihood of selection acting on them, but only for the technical reasons given in this paragraph, as well as availability.

Statistical parameters, most commonly mean and variance, are estimated for each age-group. If the age-groups differ in one or more statistics, this difference is due either to natural selection or to a difference in the environments in which the age-groups developed[2]. The latter alternative can be controlled by sampling several generations or by sampling both dead and surviving individuals. Whether or not a significant difference between age groups is found, the apparent selection intensity is then calculated for each statistic.

The intensity I_p of natural (or artificial) selection by means of differential viability, relative to statistical parameter or set of parameters p, may be defined as the minimum reduction of the original population that would yield a population with specified values of the parameter or set of parameters. This is an extension of Haldane's definition[1], and can itself be readily extended to include selection on fertility. (Both definitions actually refer to amounts, rather than intensities of selection; division by the number of generations, usually 1, converts them to intensities.) The total intensity I is the minimum reduction required to produce the total multivariate distribution for all characters and parameters after selection. I can never exceed the proportion of the original population that is lost, but can be less than this value. The derivation of quantitative estimates of selection intensity and their tabulation will be presented elsewhere.

A bias of estimation, in the direction of high intensity, exists when the difference of the means (or correlations) of the age-groups is low in relation to its standard error.

---

* NATO Postdoctoral Fellow.

This is true because the difference is taken to be positive whether an increase or a decrease in mean size has occurred, and even if no actual change took place some difference would almost inevitably be produced as a result of sampling error. The estimation of this bias is complex and the correction for it has not yet been tabulated, but in no case will the correction be as large as the estimate of intensity derived from the probable error of the difference between the age-groups. The symbol Q may be applied to the ratio of the observed difference between two age-groups, to the difference expected to occur 50 per cent of the time by chance. Q is dependent on both the power of the significance test in a given case and the level of significance reached.

If only decrease in variance is recognized (or if an increase is not recognized unless its significance-level reaches such a value as 0·01, the value I use), the foregoing bias is scarcely applicable to the variance. The ratio of the variances of the age-groups should, however, be divided by the appropriate 50 per cent F ratio to eliminate a small bias caused by different sample sizes; this produces a ratio with the same meaning as Q.

Since the age-groups available may not cover the entire time the structure under consideration was open to selection, a correction for this may be made by multiplying the observed selection intensity by the total time the structure exists before the mean reproductive age, and dividing this product by the difference between the means of the age classes. It is possible that selection may occur for the same biological reasons even when the structure under consideration is absent; but this is another matter and is perhaps more or less offset by the possibility of changes in selection intensity with age. A further correction must be introduced if the age determination of the sample is not entirely accurate.

To estimate the combined intensity for more than two age-classes, the intensity over the interval between each successive class should first be calculated. Then the first intensity should be subtracted from 1; this difference should be multiplied by the second intensity, and the product should be added to the first intensity. The resulting intensity should, of course, be used as the first one for any further accretions.

To combine estimates of intensity on two characters together, it should be noted that the square of the correlation (in the unselected population) between the characters, multiplied by the higher intensity, gives the intensity expected on the second character from the correlation only. This intensity should be subtracted from the lower intensity and the signed difference added to the higher intensity. Symbolically:

$$I_{\text{combined}} = I_1 + (1 - r^2)I_2$$

Partial correlations can be used to combine the estimates for more than two characters if desired.

As with life-tables[3], the estimate of selection intensity depends somewhat on whether the sample is of a living population (or of an entire population killed at once by a catastrophe) or of individuals that died in the normal course of the history of the population. In the latter case, but not in the former, each age-group should be added cumulatively to the next earlier one to provide the best approach to a random sample of the individuals living at the earlier age. This need not be done for the determination of the significance of differences between the age-groups, however.

The sample used here is of a Middle Miocene horse, ***Merychippus primus***, from Stonehouse Draw, Nebraska, in the collection of the American Museum of Natural History. The characteristics of the sample will be described in detail elsewhere; it is sufficient for present purposes to know that deciduous teeth can be unambiguously aged to year-groups and that, as indicated by the preponderance of young individuals and the arguments given by Kurtén[3] for this and similar samples, the specimens are probably a more-or-less random sample of a living population rather than the result of the normal attrition of mortality. Measurements of width were taken for the deciduous teeth DP^{2-4}_{2-4} and the first premolar P^2, and of lingual length for DP^2 and P^2 only. All measurements were taken at the base of the tooth and are unaffected by wear, including wear between adjacent teeth in the same jaw. The distribution in age-group I of no character differed significantly from normality, as determined by χ^2 tests against normal distributions with the same variances as the samples.

* Comparison is with age-group II.

In Table 2 the means and variances of the age-groups are compared. Although in only one case (DP^4) is the significance of the difference of the means less than the 0·05 level, it is of interest that in no case does the P value exceed 0·4, which it would be expected to do in three-fifths of the cases without selection. In the upper dentition the trend is uniformly towards smaller size, while in the lower dentition the trend between the first and second years is towards larger size and between the second and third years towards smaller size. Except for the last instance, this situation is reminiscent of that found by Kurtén[4] at a cave bear site. It is of interest that this lineage of horses was increasing in size, so the selection for smaller upper teeth indicates a temporary or local reversal of this trend. Such temporary or local reversals may well be a common phenomenon.

The intensities of selection (Table 2) required to produce the observed changes of means, as well as of variances, are remarkably high. The correlation between the widths of DP^3 and DP^4 in age-group I is $r = 0·846$. For DP^3 and DP^4 the joint intensity required to produce the observed shift of mean is $I_m = 0·44$. This means that two-fifths of the individuals in age-group I must have died simply for there to be this difference (the bias is in this case small). Similarly, combining the intensities on the mean for DP_4 over the two year-periods, the combined intensity is between 0·2 and 0·3, with a net

Table 2. INTENSITIES OF SELECTION REQUIRED TO PRODUCE THE OBSERVED CHANGES IN SAMPLE MEANS AND VARIANCES, AND SPURIOUS INTENSITIES CALCULATED FROM THE PROBABLE ERRORS OF THE DIFFERENCES OF THE SAMPLE MEANS

l refers to length and w to width

* Age-group III compared with age-group II.

Negative intensities strictly are meaningless; but they are useful in an unbiased estimation of the distribution of intensities.

result of no change in mean. These are minimal unbiased estimates of the frequency of deaths; without a sharp cut-off point the number would be somewhat higher.

P^3 is different from the deciduous premolars in that age-groups cannot be unambiguously recognized from it. (The other upper permanent teeth are excluded because they cannot be identified unambiguously at all stages of wear.) The P^3's were divided into two groups by the amount of wear. It is of interest that the amounts of selection on P^3 are ostensibly lower than those on DP^3, despite the longer interval in years between the midpoints of the age groups of P^3. Regressions of width and length on mesostyle height (a good measure of degree of tooth wear) gave values of $- 0·013 \pm 0·022$ and $- 0·036 \pm 0·032$ respectively, with Q for the regressions being 0·83 and 1·67 respectively. There is thus no evidence of selection on either dimension of P^3.

Table 3. CORRELATION COEFFICIENTS FOR AGE GROUPS OF A SAMPLE OF *M. primus*

The ratio Q is explained in the text. l refers to length and w to width

	N	r	z	Q	$P(r_1 = r_2)$

w-l P^3	32	+0·75	0·98 ± 0·19	0·86	0·50–0·60

Correlations are given in Table 3. The estimation of selection intensities for correlations is complex and not yet fully worked out; but again Q is greater than one except for P^3, indicating that correlations have probably changed as a result of selection.

The estimated intensities of selection on individual characters can be compared with the estimated mortality rate between age-groups I and II. There are 154 specimens of age-group I and 105 of age-group II, giving an ostensible mortality rate of 0·32 in this interval. This is lower (although not significantly so) than the combined estimate of I_m for DP^3 and DP^4, and is surely lower than the total I for all characters and parameters. This discrepancy can be accounted for in at least four ways. First, the distributions in age-group I may really have differed from normality, even though this could not be proved. Secondly, sampling error in the estimation of either mortality rate, selection intensities, or both, may have been in the direction to produce the anomalous effect. Thirdly, the age distribution may not have been stable; if the cohort at age II at death was more numerous when at age I than the cohort that died at age I, the real mortality rate would have been higher than that estimated. Fourthly, the differences between the first two age classes may have been due to environmental effects that differed between their years of birth, although the reduction in variance argues strongly against this. If the deaths were not catastrophic but attritional the anomalous effect would have been increased or unchanged. If a is the number in A, the first year-class; b the number in B, the second; and c the number of all older individuals C, for catastrophic death and a stable age-distribution I is estimated by comparing B with A and the first-year mortality rate by $\frac{a-b}{a}$. For attritional death and a stable age-distribution, I is estimated by comparing B with $(A + B)$, assuming B is a random sample of $(B + C)$, and will be larger than this estimate if the last assumption is false (unless the direction of selection is reversed). The first-year mortality rate is estimated by $\frac{b+c}{a+b+c}$. Comparison of these ratios shows that the first-year mortality rate is affected more than I by attritional death.

A theory of the estimation of the intensity of selection is presented and applied to teeth, mainly deciduous, of a Miocene horse. Estimates of the intensities on single characters range from zero to 34 per cent; the latter is comparable with an estimate of the mortality rate during this age interval. In older individuals the intensities appear to be lower. The intensities of selection required to produce the observed changes in means are similar to those required for the variances. Selection on the upper teeth for smaller size is opposite to the direction of phyletic change in this lineage.

I thank Mrs. Sheila Maynard Smith for helping to solve some integral equations, Mr. John Maynard Smith and Dr. Timothy Prout for discussions, and Mr. Carl Sorenson for information on the occurrence of the sample in the field. Some of the measurements were made during the tenure of a Boese postdoctoral fellowship from Columbia University with special calipers kindly loaned by Mr. Giles MacIntyre.

LONGEVITY, PALATABILITY AND NATURAL SELECTION IN FIVE SPECIES OF NEW WORLD SATURNIID MOTH

By DR. A. D. BLEST

Department of Zoology and Comparative Anatomy,
University College, London

WILLIAMS and Williams[1], following Medawar[2], have suggested that natural selection should in the majority of cases prolong the reproductive lives of animals. They show, in addition, that the force of selection must fall throughout reproductive life, to reach zero when reproduction is over; for this reason, selection cannot be held to modify post-reproductive or non-reproductive life-spans except in certain special instances. Among them may be quoted the entire life-spans and indeed the morphological specializations of the non-reproductive castes of social insects, and the survival of old members in the societies of higher vertebrates, where it is supposed that their experience is of value to the population at large; in both cases it is necessary to postulate the action of group selection. The former authors also consider that selection could in principle favour characters which are individually disadvantageous but socially useful, but conclude that the actual likelihood of such an action occurring is remote.

A possible special case has already been proposed, in which the individual disadvantageous character is an abbreviated life-span, and in which group selection either lengthens or shortens the duration of post-reproductive survival[3]. Consider two species of insect with non-feeding adults, one cryptic and palatable, the other aposematic and distasteful, and both subject to predation.

(a) The longer that a cryptic insect survives after reproducing, the greater the chance that it will be found

by a predator. Birds, at least, must learn to find individual cryptic prey species[4], and the lesson must be periodically reinforced by success. Survival, therefore, prejudices the safety of other individuals, which may still be reproductive. Group selection should shorten post-reproductive survival, and direct selection should shorten the reproductive life-span should the ecology of the species permit it to do so.

(*b*) The converse of this argument applies to the aposematic insect. Birds also learn to avoid conspicuous but unpalatable prey, and they may even do so by single trial learning[5]. The post-reproductive survival of an aposematic insect, then, should favour the survival of its siblings, for it is available to train a predator to avoid them without prejudicing the reproductive potential of the population. Group selection should lengthen the post-reproductive survival of the aposematic species; direct selection may be expected to lengthen the overall life-span.

Even if this argument were correct, there are few natural situations which will permit it to be tested. An attempt has been made to do so by using hemileucine saturniid moths in seasonal tropical evergreen forest on Barro Colorado Island in the U.S. Panama Canal Zone. In order that the species should be comparable, the five chosen for the comparison of males: (*a*) are all of the same order of size; (*b*) have all been found in their early stages within 20 ft. of ground-level beneath the forest canopy. The rather scanty available evidence implies that temperatures in the canopy itself are both higher and subject to greater fluctuations than beneath it[6], and a broader comparison would be of doubtful validity; (*c*) all five species are of approximately the same order of abundance. They are listed, together with their palatabilities to three species of predator and their defensive behaviour (summary of unpublished data), in Table 1, which includes the additional genera used in the comparison of females.

The moths were captured at an ultra-violet light trap, which was watched throughout the night; individuals were removed as soon as they arrived at the light, and inspected immediately for damage. Immaculate moths were assumed to have hatched on the night of capture, while those with wing abrasions, damage to the fringe scales or torn wings were rejected as being more than 24 h old. This procedure prejudices the adult life-tables against the hypothesis, for aposematic species tend to have hard scaling and are consequently less susceptible to mechanical damage. The male insects were stored in small plastic boxes under continuous illumination to inhibit flight activity. Moths so stored remain quiescent until they are disturbed by tactile stimulation, or until the last few days of life, when they become hyperexcitable. The flight times of male hemileucines are very narrowly restricted, often to a period of no more than 15 min in each night, and immaculate males are assumed to be virgins. Females were stored in larger cages, and were not illumined at night. The storage conditions approximated to those recorded for forest shade on Barro Colorado at a height of some 20 ft. from the ground[6]. Adult saturniids have degenerate mouth-parts and do not feed.

The adult male life-tables are presented in Fig. 1. The hypothesis predicts that the life-spans should be ranked in the following order: *Lonomia* < *Automeris* < *Dirphia*; although the two species of *Automeris* are rather distantly related, as are the two species of *Dirphia*, no prediction can be made about their order of ranking, and the data were pooled within genera for analysis by Kendall's method[7], which yields $P < 0{\cdot}0001$ for the ordered distribution. The data from male moths, then, support the hypothesis, in so far as the action of direct selection is concerned.

The results from the females are more difficult to interpret. In the first place, only a small proportion of the moths trapped at light are females. For this reason, the data for all species of female, irrespective of size, have been used for comparing the length of post-reproductive survival between palatable and unpalatable species. Secondly, it is not possible to estimate the age of females with such certainty as that of males. Female hemileucines, apart from a few exceptional species, do not fly until they have mated; if it is assumed that mating usually occurs on the night of emergence, then females replete with eggs which are captured at light must be supposed to be 24 h old. Moths so caught wait a further 24 h before starting to lay eggs, and this delay is a consequence of the method of capture, for bred moths rarely delay more than 24 h between mating and oviposition. In view of these uncertainties, the only practicable comparison is

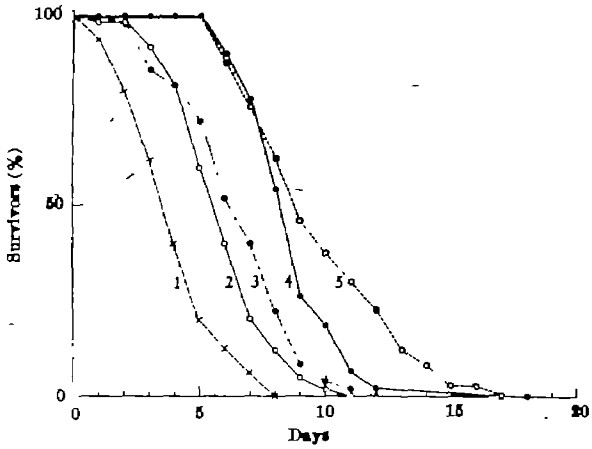

Fig. 1. Adult male life-tables for five species of hemileucine moth. Curves from left to right: 1, *Lonomia cynira* (50 males); 2, *Automeris junonia* (60), 3, *A. boucardi* (50), 4, *Dirphia eumedide* (60); 5, *D. hircia* (50)

that between survivals from the laying of the last egg to death. Such a comparison again biases the results against the hypothesis, for the trapped palatable females lay their eggs after capture and are seen to die shortly afterwards; the distasteful females are more usually captured after oviposition has been completed, and may be at any stage of their post-reproductive life-span, and such 'spent' females have been included in the data. Table 2 pools the data for each of the two classes of moth. The survivals again rank in the predicted order ($P < 0{\cdot}001$).

4	0	12
5	0	7
6	0	4
7	0	1
8	0	0
9	0	2
Total	13	45

The patterns of survival so far described are clearly 'idealized' and need bear no relation to the life-tables for feral moths. There are striking differences between the behaviour of the palatable and distasteful forms; the palatable *Lonomia*, *Automeris* and *Gamelia* spp. become increasingly excitable with age, and spend their last 12 h of life in unrestrained flight activity. Unpalatable forms (*Dirphia* (*Dirphia*), *D.* (*Dirphiopsis*), *D.* (*Periphoba*), *Hyperchiria* and *Hylesia* spp.) do not appear to undergo marked age-dependent changes in behaviour, and their excitability is relatively stable.

In the males of three species (*L. cynira*, *A. junonia* and *D. eumedide*) it has proved possible to measure these changes in behaviour with age in terms of the rocking response[8]. When hemileucine moths settle after any preceding activity they rock from side to side, and the strength of the response may be measured by the number of oscillations in a single train. For the Brazilian *Automeris aurantiaca* it has been shown that the strength of the response $y = a + bx$ where x is the duration of precurrent flight in minutes, and a and b are age-dependent constants[9]. b lies between 0 and 1·0, and relates inversely to the state of flight excitability of the individual moths. a cannot be determined for moths taken at light traps, for the previous flight history is unknown. b was measured by removing the wings and abdomens from moths of known age from capture, and subjecting them to forced tethered flight for successive 3-min periods. At the end of each period the strength of the response was measured six successive times at 1-min intervals, and the three highest values out of each group of six were used to compute b. The values of b differ slightly according to whether the moths walk or fail to walk before each settling response[9], but the difference is slight and can be ignored in the present context. Fig. 2 plots log b against age for each of the three species. By this criterion, the behaviour of the two cryptic species undergoes a continuous change with time, which is rather nicely adjusted to the adult life-span. Indeed, when $b < 0{\cdot}2$, it is virtually unmeasurable, in part because the moths have become too excitable to test, and also, arguing from the condition in *A. aurantiaca*, because a has so decreased that very long periods of flight would be needed to give real positive values to y. The age at which $b < 0{\cdot}1$ corresponds roughly to the point at which unrestrained terminal flight begins. *Dirphia eumedide*, on the other hand, behaves consistently throughout its life-span, and the increase in the excitability of flight with age is far less marked. Preliminary measurements on the aposematic species of *Hyperchiria* and *Hylesia* indicate that they share the stability of *Dirphia eumedide*.

These differences in age-dependent behaviour are likely to have certain consequences for moths in wild populations. Saturniid moths do not feed as adults, and are dependent on reserves of food which they contain at hatching. The rate at which these reserves are utilized must relate to the general excitability of the moths. High excitability associated with 'soft' scaling in the cryptic species must accelerate the obliteration of the colour patterns by mechanical damage to the wings, and simultaneously increase the vulnerability to predators. In the case of the behaviourally stable aposematic species with 'hard' scaling, the moths may be largely protected from an age-dependent increase in vulnerability. It is possible on these grounds that in Nature there is a greater disparity between the life-tables of cryptic and aposematic species than the present data would indicate; this, however, can only be determined by marking and recapture experiments.

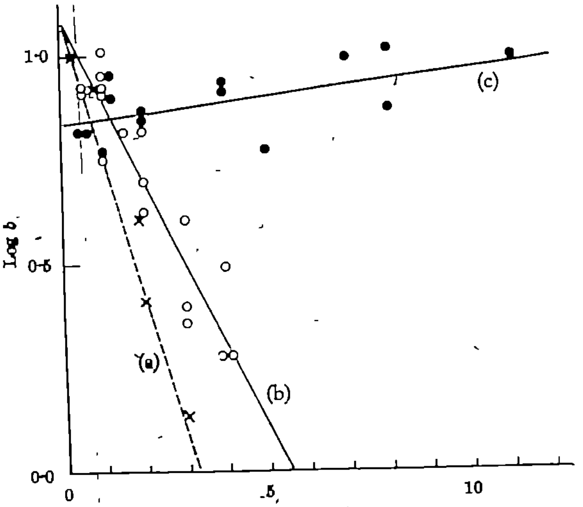

Fig. 2. Age-dependent changes in the values of b in the equation $y = a + bx$ for (*a*) *Lonomia cynira*, (*b*) *Automeris junonia*, and (*c*) *Dirphia eumedide*. Values of log b are plotted against the adult age in days

One feature of these results is of interest, for it bears on the general interpretation of ageing changes. Natural selection has been shown to have modified the adult longevities of the hemileucines studied; since the colour patterns and display behaviour of the aposematic species are the most highly elaborated in the group, and their larvæ are the most specialized, the direction of change has probably been to lengthen the life-spans from the condition found in *Automeris*. In principle, selection could modify an adult life-table of the type found for *Automeris junonia* in at least two ways: (1) The maximum age at death remains the same, but the age of onset of dying is progressively postponed. The life-table develops a plateau. The change resembles that found in the survival curves of a human population with increasing medical care[10]. For the present material, this would correspond to a hypothetical case in which the maximum adult longevity is determined by the food reserves available at hatching, which are not alterable by selection, but in which the moths are subject to lethal physiological 'accidents' with an age-dependent incidence which selection can postpone. (2) The age of onset of dying and the maximum age are shifted by an equal amount, and the rate of dying remains constant. The life-tables would resemble those found in *Drosophila* and mouse populations when breeding procedures have incidentally modified their life-spans[11].

The life-tables for the hemileucines unequivocally belong to the second category; apart from their displacement in time, they are remarkably similar. In contrast, the patterns of behavioural ageing are not homogeneous. It follows that the latter cannot be used as a fundamental measure of senescent change, whatever differential effect they may prove to exert on the mortality of wild populations. Instead, it seems that the programmed changes in the central nervous systems of the moths have been adjusted by selection to fit their overall ecology.

I thank Dr. A. R. Jonckheere for statistical advice. This work was supported by a grant from the U.S. National Institutes of Health (*RG*–7109).

BEHAVIOUR OF YOUNG *OCTOPUS BRIAREUS* ROBSON

By J. B. MESSENGER

Department of Anatomy, University College, London

OCTOPUS briareus is of interest to students of cephalopods as it has no pelagic larval stage in its development: the young, which emerge from large eggs, are benthic from the moment of hatching. As they are relatively large, their behaviour can be usefully compared with that of an adult octopus. This species, described first by Robson[1,2], and later, more critically, by Pickford[3,4], is a shallow, warm-water form from the Caribbean, common along the Florida Keys[5]. This article reports observations made on living adult and young *O. briareus* at the Marine Laboratory of the University of Miami in April 1962.

A female, of mantle-length about 60 mm, and her clutch of eggs had been taken locally and installed in a tank with running sea-water. There were about 130 eggs, each with a long (10-mm) stalk: bunches of up to about 20 eggs were formed by the individual egg-stalks twisting around one another to form a long (18 mm) greenish strand, which attached the eggs to a rock. The bunches hung down in the water and they were closely guarded by the female, who refused to feed or leave the eggs during the period of observation. She continually agitated them by movements of the arms and body. The eggs were pearly, by reflexion, and semi-transparent, so that it was possible to see the chromatophores on the body of the unhatched animal: the empty egg-cases were white.

It has been estimated that *O. vulgaris* lays about 150,000 eggs[6], each about 2·5 mm long, which produce larvæ of about 1·5 mm[7]. It is interesting to note, therefore, that *O. briareus* produces far fewer eggs, the dimensions of which are relatively enormous. The empty egg-cases measure 12 mm × 6 mm, excluding the stalk; the newly hatched animals have an arm-span of almost 17 mm and a mantle-length of about 5·5 mm and are, in their bodily proportions, smaller versions of an adult octopus and quite unlike the planktonic larva of *O. vulgaris*. Hatching was observed in the laboratory and although it was probably premature, the behaviour observed confirms Voss's observations[5] that the animals never pass through a planktonic stage.

The young animals emerge backwards from the lower, blunt end of the pyriform egg and immediately swim or crawl downwards, often blowing ink at the same time. They have conspicuous eyes, often surrounded by a dark ring, and they change colour as rapidly as adult octopuses. There are fewer chromatophores per unit area than in the adult, so that the animals have a speckled appearance; there is a conspicuous double row of large chromatophores down each arm. Waves of chromatic activity can be elicited by sudden movements of the observer at distances of up to 2 ft., and rapid approach of a hand is followed by reflexion of the arms, paling and spreading of the interbrachial membrane. This 'dymantic response'[8] thus appears to be innate. It is conceivable however that it is acquired during the last stages of life in the transparent egg, although the usefulness of such a response then is not very obvious. It is noteworthy that in *Sepia*, which has an opaque (black) egg, no dymantic response has been observed in very young animals[9].

The newly hatched young seldom move, and usually sit, with head uppermost, on the side wall of the aquarium at the air-water interface, sometimes half out of the water. Commonly the arms are spread backwards and gathered around the body, so that the outline of the animal is roughly circular. When disturbed the animals walk away rapidly and jerkily; they may eject ink. Only rarely do young *O. briareus* swim. This might be because of their innate tendency to cling strongly to a surface, here usually vertical, a tendency which, together with their ability to change colour, must afford them considerable protection from enemies. Indeed, the very fact that *O. briareus* lays so few eggs suggests that the survival rate of the young is very high; large numbers of eggs are laid not only by *O. vulgaris* but also by other octopods producing planktonic larvæ[10]. Certainly the tendency to adhere to a surface is so marked in *O. briareus* that it was possible to lower the water-level in their tanks gradually without causing the animals to move down with it, even though this resulted in their being left completely high and dry.

The feeding behaviour, too, reflects this tendency to remain attached; the animals always seized the prey with a few arms and anchored themselves with the remainder. They never swept down on the prey like adult octopuses and indeed many feedings were the result, not of an attack by the octopus, but of the prey accidentally entangling itself with some of the arms. When this

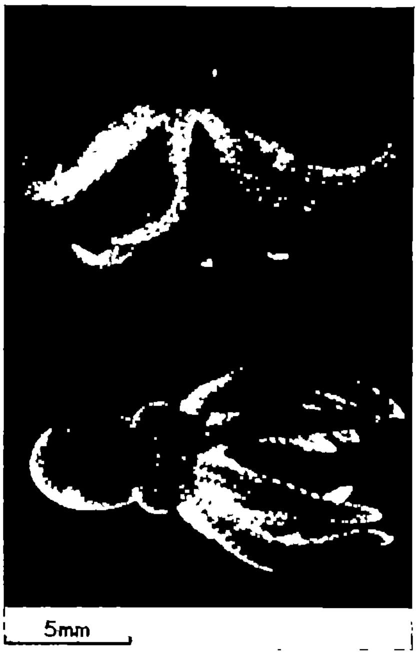

Fig. 1. Above, fixed specimen, 16 days old note the prominent eye, large funnel and conspicuous chromatophores; below, fixed specimen, 2 days old, showing the double row of large chromatophores down each arm and the well-developed suckers

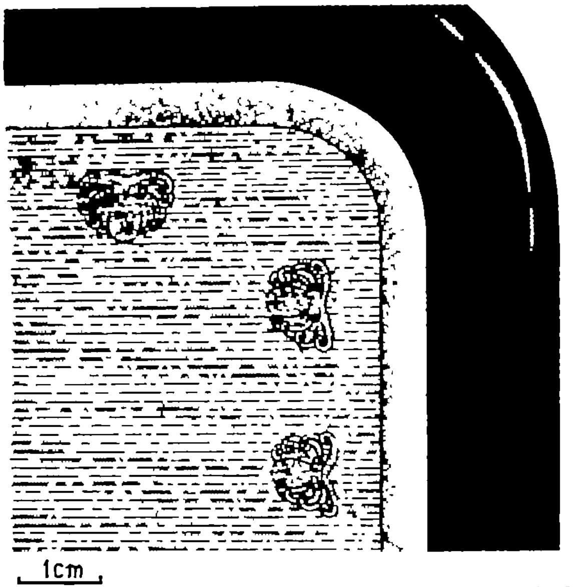

Fig. 2. Drawing, from Kodachrome transparencies, of living animals —6 days old—in a typical resting position

happened other arms would be brought round to the prey to pass it under the large interbrachial membrane in the usual way, in which process the octopus might let go of its substrate for a moment. Although the animals rarely attacked living prey, they could be relatively easily 'force fed'. In 'force feeding' a very small piece of freshly killed shrimp was offered to an arm with fine forceps or at the end of a fine thread. The arms and suckers explored the meat and the arm quickly passed it under the web to the mouth.

Live food comprised crustaceans, less than 10 mm in length, such as *Latreutes fucorum*, *Leander* sp., *Hippolyte* sp., and some unidentified amphipods; *Artemia* (young and adult) were also tried, but, like the other species, never elicited 'good' attacks. Nor did offering them result in any obvious visual fixation of the kind visible in *Sepia* when they are presented with mysids.

Adult *O. briareus* eat bottom-shrimps, bivalves, crabs, probably gastropods and occasionally polychaetes[11], but nothing is known about the diet of the young animals though this is of critical importance if rearing these animals in the laboratory is to be done or if behavioural investigations are contemplated. In this latter context it is unfortunate that the question of innateness of response by *Octopus* to crabs could not be clarified as it is of some importance[12]: no crabs small enough to present to these octopuses as food were found, however.

No yolk sac was visible at hatching (although the eggs hatched prematurely) so that we might expect the young to start feeding at once unless there was a sufficient supply of yolk internally to last for a day or two. No experimental evidence for this was forthcoming; indeed the animals seemed no more likely to attack the food offered after ten days than after two, or after several 'force feedings'.

That attacks were so rare may have been because of failure to offer the natural food; but it would be unwise to assume that the choice of prey is highly specific (cf. *Sepia*[13]). The animals might be scavengers and detritus feeders at this stage.

Generally young *O. briareus* are very inactive and only two other types of behaviour deserve mention. First, 'attention' movements[14]—raising and lowering the head several times in rapid succession—were seen on some occasions, generally coincident with movements of the observer. Secondly, two octopuses were sometimes seen to approach one another head on, and entangle the arms, which flailed wildly. Changes in colour occurred, but no consistent pattern of change was seen.

In Europe, the behaviour of adult *O. vulgaris* has been the subject of intensive analysis, but the larvæ, because they are planktonic and minute, are difficult to examine: it is therefore impossible to assess the relative importance of innate and acquired components in the behaviour of the adult, although this is clearly of great significance. This difficulty does not arise in *Octopus briareus*, and if more could be learnt about the food requirements, so that the young could be reared in the laboratory, this species might be an ideal one for workers investigating the innate components of behaviour in octopods.

This work was done while I was in the Department of Zoology, Yale University, New Haven, Conn. I thank the Fulbright Commission for providing a grant for travel to the United States, and Dr. Grace E. Pickford for her considerable help while I was at Yale. I also thank Dr. G. L. Voss and the Director and staff of the University of Miami Marine Laboratory for their kind help and hospitality, and Prof. J. Z. Young, and Mr. B. B. Boycott for their helpful comments on the manuscript.

NEW FOSSIL HOMINOID MATERIAL FROM UGANDA

By PROF. DAVID ALLBROOK
Makerere University College
AND
DR. W. W. BISHOP
Uganda Museum, Kampala

UP to 1962, the published record of large hominoid fossils of Mid-Tertiary age was limited to ten specimens consisting of teeth and mandibular fragments found in Kenya. Six of these were designated *Proconsul major* by Le Gros Clark and Leakey[1], and the other four provisionally ascribed to *P. major* by Le Gros Clark[2]. Of these ten pieces unfortunately only two specimens, single left and right M^3, represent the upper dentition.

In Uganda a single right upper canine collected in 1958 from Napak (34° 17′ E., 2° 5′ N.) has been assigned recently to *P. major* by Leakey[3].

In August 1961 an expedition from the Department of Geology, University of Glasgow, visiting Karamoja District, Uganda, collected five further hominoid specimens at Napak and two specimens from a locality to the north of Moroto Mountain (34° 45′ E., 2° 32′ N.). The

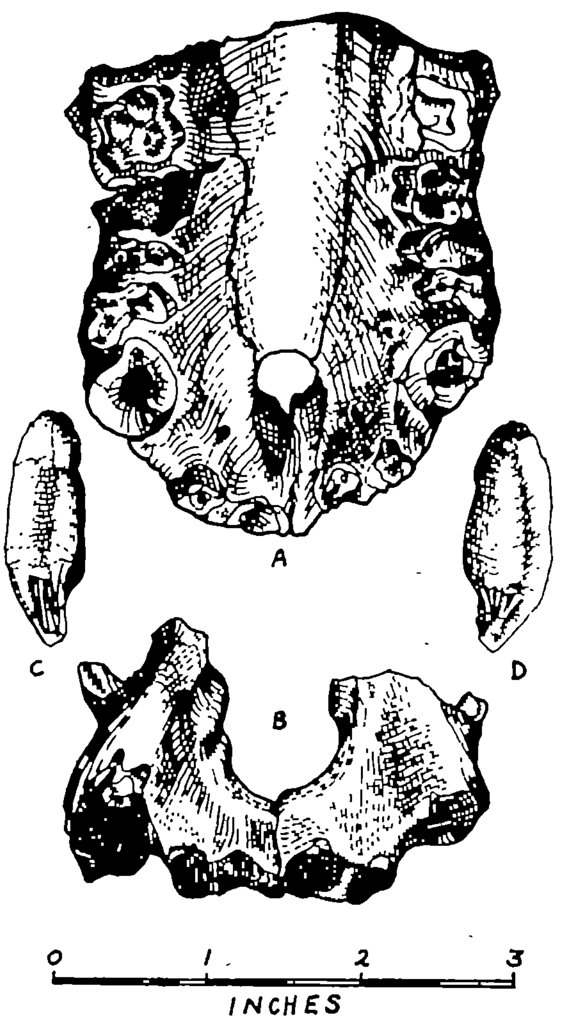

Fig. 1 Specimen *UM P*.62-11 in palatal view (*A*) and front view (*B*). Specimen *UM.P*.62-12 in labial view (*C*) and lingual view (*D*) (Drawings by Mr. W. Serumaga)

preliminary stratigraphical and palæontological results of the expedition and the location of the sites have already been described by Bishop and Whyte[4].

In December 1961 a party from the Department of Anatomy, Makerere University College, re-visited the Moroto site and recovered four additional fragments of the upper dentition of a large hominoid. Three of these pieces and one of the specimens recovered during the Glasgow expedition (all of which were found on the surface within a few feet of each other) proved to be contiguous left and right maxillæ and two other adjoining fragments from a single individual. The fragments have been joined together and registered as one specimen (*UM.P*.62-11).

In August 1962 a party of the Brathay Exploration Group visited Napak and found the broken crown of a large primate molar.

Thus, a total of ten specimens of large fossil hominoid, many of them representing the upper dentition, are now known from Uganda localities. They are registered in the collections at the Uganda Museum, Kampala (*UM.P*.62-03 *et seq*.). The purpose of this article is to give a preliminary description of this material, which comprises the reconstructed maxillæ together with two other pieces from Moroto and seven specimens from Napak.

The Glasgow expedition was financed by a Royal Society scientific grant-in-aid and the Makerere College work by a grant from the Wenner-Gren Foundation for Anthropological Research and the Wellcome Trust, to whom grateful acknowledgment is made. We are indebted to Sir Wilfred Le Gros Clark, Dr. L. S. B. Leakey and Mrs. S. Coryndon for helpful comments and criticism, and to members of the Anatomy Department, Makerere University College, in particular, Dr. E. C. B. Hall-Craggs for practical assistance.

(1) Specimen *UM.P*.62-11, Moroto II, August and December 1961

Osteology. The reconstructed specimen is undistorted and comprises most of the middle facial skeleton and a part of the upper dentition. The reconstruction is made up of two large fragments and two smaller fragments from either side. The specimen consists of the lower part of the nasal aperture, the incisor region, the maxillæ on both sides as far back as M^2, and the palate, excepting the median 1/3 caudal to the incisive canal (Fig. 1*A* and *B*).

There is an intermaxillary suture. The incisor bearing premaxilla is wide, relative to the bicanine width but is relatively short rostrocaudally. Diastemata are present between the medial and the lateral incisors and the latter and the canines. Sub-nasal prognathism is not marked. The presumed middle part of the nasal aperture is the widest. Its margin at the midline smoothly leads on to the external alveolar surface of the premaxilla. Only in the infero-lateral margin of the nasal aperture is there the beginning of an edge. Canine fossæ are just discernible, but the external aspect of the maxilla is rounded and filled out because of the massiveness of the canine roots. The external and medial face of the right premaxilla is roughened and the incisive fossa and prominance for the root of the medial incisor (obvious on the left) is not present. The maxillary sinuses extend rostrally to the level of P^4 and are still large at the anterior roots of M^2. The palate is shallow but the palatal processes are thick opposite P^4 (8 mm) and are still 4 mm thick at M^2. The inferior meatus is deep (average of 12 mm) and wide (27 mm at M^2-level). The incisive canal is large even though the caudal border on one side is incomplete. It averages 6·5 mm in diameter. The partial remains of the maxillary-premaxillary suture are visible. The width of the palate at the level of the canine teeth is 37 mm, at P^3 (the widest part) it is 39 mm, and the estimated width at M^2 is 35 mm.

Dentition. All the incisors and both canines are broken near the alveolar margin. The roots of the left incisors are stout, especially in the anterior–posterior direction and the alveolar spaces between them suggest that they had spatulate crowns. On the right the medial incisor root is small and fragmented. On the left, the apex of the root of the canine is exposed as a small disk embedded in dense maxillary bone. Both pre-molars are broken at the alveolar margin, the roots only of M^1 are present, the whole of M^2 is preserved and the anterior sockets of M^3 are present. On the right P^4 and M^1 are complete but show moderately advanced attrition, obscuring the details of the cusp pattern. M^2 is broken level with the alveolus and the anterior labial socket of M^3 is present. It is, therefore, possible to reconstruct tentatively the position of the upper dentition in which the sides of the arch are parallel or may even converge a little posteriorly.

The dimensions of the teeth are given in Table 1.

The premolars are narrow antero-posteriorly as they are in *Proconsul* maxillary specimens *R*.1948, 50 (*R*.106) and *CMH*.2. Right P^4 is stout though the roots are not so robust as those of P^3. The principal (labial) cone exceeds

Table 1. TEETH OF SPECIMEN *UM.P* 62-11

the worn deuterocone in height by 3·5 mm and is connected to it by a single ridge. An anterior and an external cingulum are present, though not very distinct. The dimensions are larger than P^4 in *Proconsul nyanzae* (*CMH.2*) though the proportions are similar.

Right M^1 is stout and worn. The worn concavity in the position of the protocone dominates the abraded surface of the crown and the cavity in the position of the hypocone is half its size. The metacone is relatively unworn and the paracone is low, flattened and unworn. The internal cingulum has been removed by attrition. The dimensions are greater than in the corresponding tooth of *CMH.2* (Table 3).

Right M^2 is broken at the cervix, and the medial roots are also absent. Left M^2 has a prominent crenated internal cingulum, an external cingulum, a large worn protocone, small unworn paracone, metacone conical and unworn and a large worn hypocone. The tooth is similar in morphology to M^2 in *CMH.2* of *P. nyanzae* though larger, but is smaller than *CMH.35* (*S*) and *S*.381'49 provisionally assigned to *P. major* by Le Gros Clark and Leakey[1,3] (Table 3).

*Discussion of UM.P.*62-11. By comparison with palatal and maxillary dimensions of modern gorilla and chimpanzee material, it is probable that the individual was of generally similar size to a full-grown female gorilla.

The freedom from post-mortem distortion of *UM.P.*62-11 is of particular importance. Unfortunately, both of the adult specimens of *P. africanus* (*R*.1948,50,*R*106) and *P. nyanzae* (*CMH.2*) which are relevant for comparison have suffered some post-mortem deformation. This raises doubt as to the original morphology of the face and palate. Such does not apply to the juvenile specimen (993.1947) of *P. nyanzae* described by Le Gros Clark and Leakey[1], or to the sub-adult maxilla of *P. africanus* (*Rs*.51/1499) described by Napier and Davies[5]. The slight malformation of the right premaxillary region in *UM.P.*62-11 does, however, result in some distortion of this side of the inferior nasal aperture.

With this caveat, comparison indicates the following skeletal and dental features in which the present specimen is similar to, or differs from, the *Proconsul* specimens so far described.

(1) Comparison of the dental arcade with the known adult forms of *Proconsul* is not valid because of the distortion of the latter. The arcade resembles that of the juvenile *P. africanus* and *P. nyanzae* in that the lines of the cheek teeth appear parallel or may even converge slightly posteriorly (*vide* Plate 2 of ref. 5). A similar-shaped arcade is found in modern cercopithecoid monkeys.

(2) The palate is shallow. It is deeper in the specimens of *Proconsul africanus* (*R*.1948,50,*R*106) and *P. nyanzae* (*CMH.2*) but these have suffered compression or shearing of the palatal bones.

(3) The nasal aperture is distinctly less cercopithecoid than the available adult *Proconsul* specimens. Although not like a modern cercopithecoid monkey neither is it typical of a modern adult pongid. It is most similar in form to that of a young chimpanzee, in which the morphology of the nasal aperture is not obscured by the need to buttress the stout, curved canine roots found in the adult.

(4) The external maxillary surfaces are smoothly curved to accommodate the straight and robust canine roots. There are barely discernable external depressions just lateral to the canine roots (the canine fossæ). In the *Proconsul* specimens both canine and incisive fossæ are present although in the sub-adult *Rs*.51/1499 described by Napier and Davies[5] they are shallow.

(5) Sub-nasal prognathism is slight. The skull of *P. africanus* from Rusinga was described as prognathous but this feature 'may be slightly exaggerated by warping' as noted by Le Gros Clark and Leakey[1] and discussed further by Robinson[6]. In the sub-adult *Rs*.51/1499, prognathism is less pronounced.

(6) The incisive canal is large and resembles that of the modern cercopithecoid monkeys. The deformed palate of the adult *Proconsul africanus* of *Rs*.51/1499 is cercopithecoid in appearance.

(7) Comparison of the dental characteristics with those in named *Proconsul* specimens shows marked similarity. The sections of the roots of the broken canines are narrowed in the labila-lingual direction and are similar to the canine tooth (*UMP*.62-03) ascribed to *P. major* by Leakey[3]. The proportions of the pre-molars are similar to those of *Proconsul*, showing antero-posterior narrowing and the cusps, though worn, are also characteristic. The cusp patterns of the molar teeth are like those ascribed to the genus. The dimensions of the cheek teeth are all greater than those of *P. nyanzae* (Tables 2 and 3).

Holotype of *Proconsul nyanzae* *CMH.2* Average M^1	9·0	11·5	128	6·0
Average M^2	12·0	13·0	108	6 0

The dental characters of *UM.P.*62-11 are compatible with the diagnosis of a large form of the genus *Proconsul*, while the bone morphology is cercopithecoid though still compatible with the genus *Proconsul*.

In view of the variability of the skeletal morphology in the modern anthropoid apes, it seems desirable to avoid setting up new genera for their fossil antecedents until there is clear comparative evidence that a new genus (or even species) is required. This is particularly true in view of the limited material available and until topo-typical maxillary specimens of *Proconsul major* are found from Songhor in Kenya.

With this proviso the specimen *UM.P.*62-11 is provisionally assigned to *Proconsul major*, which was defined by Le Gros Clark and Leakey as 'approximating in size to a gorilla' with the definitive feature being 'the great size of the teeth and mandible' by comparison with *Proconsul nyanzae*[1].

The qualifying statement of Le Gros Clark, concerning the difficulty of assigning to a particular taxon, isolated teeth and small fragments, might well be repeated here[2]. However, for similar reasons to those given above for *UM.P.*62-11, the following nine specimens are also provisionally assigned to the species *Proconsul major*.

(2) Specimen *UM.P.*62-10, Moroto II, August 1961

A fragment of massive right mandibular ramus. The dimensions of the specimen measured at the base of the ascending ramus are *AP*. 31·9 mm, *Tr*. 22·8 mm. The maximum depth of the broken mandible is 24·2 mm. M^2 and M^3 have been broken level with the alveolus. The maximum transverse width of the socket of M^2 is 12·8 mm and of the anterior socket of M^3 13 mm.

(3) Specimen *UM.P.*62-12, Moroto II, December 1961

A little worn left upper canine broken slightly at the tip of the root and having a length of 51 mm (Table 2). It is identical in morphology to the description given by Hopwood[7] in referring to the type canine of *Proconsul africanus* but is approximately one and a half times as large (Fig. 1*C* and *D*). Cross sections of *UM.P.*62-12 drawn in the same plane as the upper and lower fractures of the roots of the canines in *UM.P.*62-11 are similar in size and form to this specimen.

(4) Specimen *UM.P.*62-03, Napak I, June 1958

A right upper canine slightly broken at the distal and proximal ends and having an actual length of 46 mm. Reconstruction suggests that the original length was probably about 52 mm (Table 2). The morphology is similar to the Moroto II canine *UM.P.*62-12, but the tooth shows pronounced wear facets on the posterior and antero-lingual faces of the crown. This specimen has been attributed to *Proconsul major* by Leakey[3].

(5) Specimen *UM.P.*62-04, Napak V, August 1961

A right upper canine slightly broken at the tip of the crown having a reconstructed length of 56 mm (Table 2). Very similar in size and morphology to *UM.P.*62-03 and 62-12 but with a rather more robust root.

(6) Specimen *UM.P.*62-05, Napak V, August 1961

Left upper canine. The left counterpart of *UM.P.*62-04 and identical in morphology in every respect (Table 3). Cross-sections of these two canines at the appropriate levels are almost identical to those of the broken canines of *UM.P.*62-11 (Table 2).

(7) Specimen *UM.P.*62-06, Napak V, August 1961

A fragment which is tentatively ascribed to *P. major* consisting of the anterior left mandibular ramus of a juvenile, broken in the region of the symphysis. The specimen has been badly broken along the alveolar margin exposing the unerupted left I^2. The broken socket of the left canine is visible together with fragments of the broken roots of the deciduous cheek teeth. The unerupted germ of what is possibly M^1 can be observed deep in the mandible through a break in the bone. The maximum depth of the mandibular fragment is 28 mm and its total thickness 15 mm. The symphysial region shows the beginning of rostro-caudal thickening but there is no evidence of a simian shelf. The unerupted incisor has a crown height of 13 mm and is markedly triangular in A.P. section. The transverse width of the biting edge is 6·0 mm and the A.P. width at the base of the crown is 7·0 mm.

(8) Specimen *UM.P.*62-07, Napak V, August 1961

A right first upper molar exhibiting moderate wear of the cusps. The lingual root is present, although broken at the tip, and is widely splayed laterally. Both anterior and posterior pressure facets are present. Although the tooth is considerably less worn its cusp pattern and proportions are similar to the right M^1 of *UM.P.*62-11. In general morphology it recalls *CMH.*35, tentatively designated right M^2 (?) of *P. major* by Le Gros Clark and Leakey (Table 3) and it is considerably larger than M^1 in the holotype of *P. nyanzae*.

(9) Specimen *UM.P.*62-08, Napak V, August 1961

The crown of a left upper second molar showing moderate wear and with well-marked anterior and posterior pressure facets. The details of the morphology agree perfectly with the description of the left M^2 *S.*381′49 provisionally ascribed to *P. major* by Le Gros Clark[2]. The Napak tooth is rather larger but the indices are identical (Table 3). It is larger than M^2 of *UM.P.*62-11 and rather less worn, but again there is a pronounced similarity in the details of the tooth morphology and in the indices.

(10) Specimen *UM.P.*62-09, Napak I, August 1962

Fragment of the crown of an unerupted left molar (? M^2), comprising approximately the labial half of the crown. A pressure facet is present on the anterior aspect of the tooth, but the deeply crenated cusp enamel of the occlusal surface shows no sign of wear. The anterior-posterior measurement of the tooth is 15 mm and as the cusp pattern resembles that of *UM.P.*62-08, the fragment is also tentatively ascribed to *P. major*.

Distribution

P. major has been found at four sites. On Rusinga Island from a total of 124 specimens of *Proconsul* only two teeth are attributable to *P. major* while at Songhor the proportion is eight teeth or jaws of *P. major* from a total of 37 *Proconsul* specimens. At Napak the total is 7 finds of *P. major* from a total of only 10 *Proconsul* remains; at Moroto all three primate finds (or 6 pieces prior to reconstruction) are of the large species. At the last two sites the totals are small and are undoubtedly over-shadowed by the occurrence of several pieces representing one individual. However, the lack of many specimens of the large species at Rusinga, the rise to almost 25 per cent at Songhor and the dominance of *P. major* at the two Uganda localities may imply variations in the abundance of this creature possibly resulting from different ecological conditions.

Conclusions

Ten primate fossils found at Mid-Tertiary sites in Karamoja, Uganda, are provisionally assigned to *Proconsul major*.

The bones are thick and massive but the morphology has cercopithecoid features. The upper canine teeth are pongoid and are similar in form to those of *Proconsul africanus* although larger, having stout uncurved roots. The available upper canines of *P. nyanzae* appear to have narrower roots and rather higher crowns. The cheek teeth cusp patterns and crown proportions are precisely those of the genus *Proconsul* in every major particular. When allowance is made for sexual dimorphism and the fact that the two sites of Moroto and Napak are more than 50 miles apart and possibly do not represent precisely contemporaneous periods of fossilization, the material can be seen to constitute a remarkably homogeneous series of specimens.

LETTERS TO THE EDITOR

PHYSICS

A Direct Terrestrial Test of the Second Postulate of Special Relativity

THE following is a preliminary report of an investigation performed to test directly, in a terrestrial experiment, the second postulate of special relativity, which states that the velocity of light is independent of the motion of the light source. A direct test means here that the velocity of the light from a moving source is measured by a time-of-flight technique and not by use of interference effects in a closed light path or a frequency measurement. Investigations of the last-mentioned type may lead to difficulties in the interpretation of the result and are therefore not very satisfactory, as pointed out by, for example, H. Dingle[1].

In testing the second postulate it may be of advantage to use γ-radiation instead of ordinary light. One should thereby avoid possible effects caused by interaction between the light and stationary material situated between the source and the detector, as discussed, for example, most recently by J. G. Fox[2]. According to this author it may be that older evidence for the second postulate obtained from ordinary light experiments as, for example, the well-known double star evidence, are impaired with systematical errors which would weaken their reliability.

The principle of the investigation here undertaken was to measure the velocity difference between γ-rays from recoiling nuclei and nuclei at rest.

The moving γ-ray source was ^{12*}C excited in the reaction ^{12}C$(\alpha,\alpha')^{12*}$C and the γ-ray source at rest was ^{16*}O from the reaction ^{16}O$(\alpha,\alpha')^{16*}$O. The 14-MeV α-beam and the time-of-flight equipment of the 80-cm cyclotron of the Nobel Institute of Physics were used for the measurement[3]. The targets were placed at 30 cm from each other in the beam direction and could be interchanged in a few seconds. Half the beam intensity was used for the ^{12}C target and half for the ^{16}O target. The time delay between the irradiation of the two targets was about 12 ns.

As the half-life of the 4·43-MeV level in ^{12}C is $6 \cdot 5 \times 10^{-14}$ sec (ref. 4), the γ-ray is emitted before the nucleus has been stopped. The half-life of the 6·13-MeV level in ^{16}O, on the other hand, is $1 \cdot 2 \times 10^{-11}$ sec (ref. 4), so that the nucleus is at rest when this γ-ray is emitted. Doppler shift measurements with a sodium iodide crystal showed that the mean forward velocity of the recoiling ^{12}C nucleus was $(1 \cdot 8 \pm 0 \cdot 2)10^{-2}$ c, where c is the velocity of light in vacuum. In the case of ^{16}O the Doppler shift measurements confirmed that the nucleus was stopped before emission of the 6·13-MeV γ-ray. A small amount (< 15 per cent) of 7-MeV γ-rays from ^{16}O was also present. The influence of these on the measurements could be corrected for, however.

In the time-of-flight experiment the γ-rays were detected by a liquid scintillator (5 in. × 2 in.) located at a mean distance of 5 m from the target arrangement and at an angle of 10° with respect to the α-beam. A small plastic scintillator, placed at 1 m from the target arrangement, was used in parallel with the large detector to give reference peaks in the time spectra.

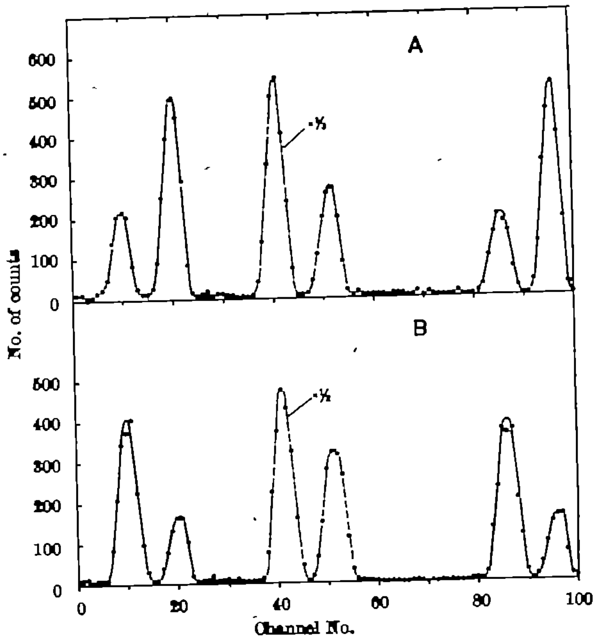

Fig. 1. Time-of-flight spectrum of the γ-rays detected in the small counter (dashed curve) and large counter. Channel width, 1·1 ns. *A* shows the case when target ^{12}C is first reached by the beam; *B* when the two targets have been interchanged

In Fig. 1*A* is shown an example of a time-of-flight spectrum when target ^{12}C is first reached by the beam. Fig. 1*B* shows the case when the targets have been interchanged. The small detector gives rise to the two peaks in the middle of the spectra while the large detector is responsible for the two other groups. The distance between these corresponds to one cyclotron period. If the distance between the centre of gravity of the two peaks in each group is τ_1 in Fig. 1*A* and τ_2 in Fig. 1*B* then $\tau_1 = \tau_2$ if the velocity of the γ-radiation is independent of the motion of the source. On the other hand, if the velocity of the γ-rays is $V = c + kV_s$, for example, then $\Delta\tau = \tau_1 - \tau_2 = 2S \times V_s \times k \times c^{-2}$, where k is a constant and V_s the source velocity. With $k = 1$ and $S = 4$ m (the distance between the two detectors), $\Delta\tau$ would be 0·5 ns.

From several different runs the following mean value has been found:

$$\Delta\tau = -0 \cdot 2 \pm 0 \cdot 2 \text{ ns}$$

A systematical deviation (in both detectors) of $\Delta\tau$ from zero, independent of the source to detector distance, was present. This systematical error causes the uncertainty of the measurements to be somewhat larger than that predicted from time resolution of the equipment and statistics alone. It is hoped that this systematical error will be eliminated in the continuation of these measurements of which a more detailed report will be given in *Arkiv Fysik*.

The result of this investigation is in agreement with the second postulate but does not agree with the result of a recent work by W. Kantor[5]. It would certainly be of interest to perform a test where the source velocity is larger than that used in the present measurement, as, for example, with a π^0-source as suggested by, among others, W. G. V. Rosser[6].

We thank Prof. O. Klein and Dr. K. G. Malmfors for valuable discussions.

Change in Velocity of Light emitted by a Moving Source

SOME interest has been aroused recently by a paper by W. Kantor[1], describing an experiment to detect the change in the velocity of light emitted by a moving source. The author explains his results on the hypothesis that the velocity of light as it leaves the moving surface of a glass block through which it has been transmitted is given by the expression $c' = c + \rho v$, where c is the usual velocity of light, v the velocity of the glass surface in the direction of motion of the light beam, and ρ is some constant, equalling 1 on classical theory and 0 according to relativity. The experiment described then shows an effect which can be explained by assuming $\rho = 2/3$.

We have recently constructed an apparatus to test this hypothesis. White light is passed through a slit and is then collimated. It then passes through a semi-circular disk of glass which is rotated by a high-speed electric motor about an axis in its own plane, the axis of rotation being normal to the direction of motion of the light beam. It is then possible to show quite simply on the foregoing hypothesis that the wave front emerging from the apparatus will be moving more slowly on one side than on the other, and so should rotate as it is propagated.

The light was received in a telescope which could be placed at different distances from the apparatus, and the deviation of the light could then be detected by comparison with the image which had not passed through the disk. The angle of deviation is $\theta = \rho w x / c$, where w is the angular velocity of the glass disk, and x is the distance of the telescope from the disk.

Under the conditions of our experiment $w = 1{,}500$ ($= 14{,}300$ r.p.m.), x, the distance of the telescope from the disk $= 20$ m, and $c = 3 \times 10^{10}$ cm/sec, so that if $\rho = 1$, $\theta = 20$ sec of arc. This is of course easily detectable in a moderate-sized telescope, and in our case the minimum angle detectable was 0·5 sec, the limit being set by the size of the diffraction pattern seen in the telescope.

At no time was any deviation of the light observed and we conclude that ρ in this case is less than 0·025, if indeed it is different from zero.

Special relativity predicts a small effect of 0·0008 sec of arc due to Fresnel drag in the glass, but this deviation is too small to be detected by this technique.

Sub-sieve Sizing by Sedimentation Balance

IN determining the size distribution of particles in samples of finely ground barytes, difficulties have been experienced in determining experimentally the ultimate balance reading corresponding to sedimentation equilibrium[1]. It takes an inordinately long time for equilibrium to be attained, and even then this does not necessarily represent complete sedimentation of all solid particles. Consequently, even at equilibrium the balance reading (S_∞) will be less than the theoretical maximum reading corresponding to the weight of solid introduced (S_m).

In these circumstances, sub-sieve sizing by sedimentation balance can become a protracted and inconvenient operation if the conventional gravimetric methods of determining S_∞ and S_m are adopted. However, some preliminary success has been achieved in these laboratories by using forms of exponential functions to determine S_∞, permitting termination of the experiment long before sedimentation equilibrium is attained and also obviating any need to evaporate liquid and weigh dry samples.

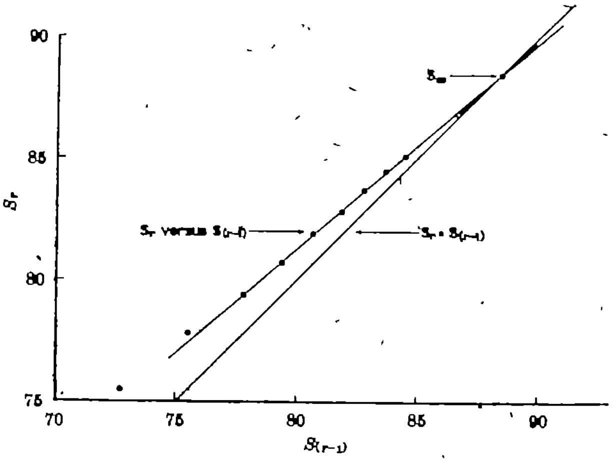

Fig. 1. Graphical determination of S_∞ ($\Delta = 5$ min)

It is our experience that in many cases the upper 10–20 per cent of the sedimentation curve can be described by the equation:

$$S = S_\infty (1 - e^{-bt}) \tag{1}$$

where t is time, S is the balance reading and b is a rate constant.

This equation may be represented by the pair of equations:

$$t_r = t_{(r-1)} + \Delta \tag{2}$$

and

$$S_r = S_{(r-1)} \cdot e^{-b\Delta} + S_\infty (1 - e^{-b\Delta}) \tag{3}$$

where r is an integer and $\Delta > 0$ and is constant[2].

A solution of equation (3) is $S_{(r-1)} = S_r = S_\infty$, and by plotting S_r against $S_{(r-1)}$, S_∞ is readily obtained; b is not of significance in this instance. The experimental results given in Table 1 are plotted in this manner in Fig. 1; the point of intersection of the experimental line, S_r versus $S_{(r-1)}$, with the theoretical line, $S_r = S_{(r-1)}$, is the value of S_∞.

In Table 1, the times from 5 min onwards advance in arithmetic progression in accordance with equation (2). The usual experimental technique is to take balance readings at times advancing in geometric progression; in this case, suitable values for plotting according to equation (3) are obtained by graphical interpolation. Additionally, interpolation has the advantage of smoothing instrument reading errors. Having determined S_∞, the size distribution is determined in the usual manner[3].

Table 1. SEDIMENTATION BALANCE READINGS FOR CLASSIFIER OVERFLOW PRODUCT (BARYTES)

Time (min)	Scale reading (S)	Time (min)	Scale reading (S)
0	0·8	30·0	75·5
1	4·8	35·0	77·8
2·5	14·8	40·0	79·4
5·0	31·2	45·0	80·7
7·5	43·7	50·0	81·9
10·0	52·2	55·0	82·8
15·0	63·3	60·0	83·7
20·0	68·3	65·0	84·5
25·0	72·7	70·0	85·1

($S_\infty = 88·5$ from Fig. 1)

This procedure has been used successfully in this Department to analyse a number of sedimentation balance curves and has also been used in other similar applications[4]. The curves were related to separations according to particle size in a sedimentation classifier, and it has been logical throughout to relate sizing analyses to that proportion of the solid in suspension which would settle; that is, to S_∞ and not S_m. Results obtained by other workers have been examined successfully by the same procedure.

In some instances the plot of S_r versus $S_{(r-1)}$ does not give a straight line, but the curve obtained would probably fit another function having an unknown asymptote. In the case illustrated, the plot is linear over the last 12 per cent of the sedimentation curve; but curvature becomes apparent if the relationship is plotted over a wider range of balance readings.

This point is at present being investigated and further results are being analysed.

Very Precise Thickness Measurement of Thin Films

IT has already been pointed out[1] that the Smith type of interference microscope, using a Wollaston prism in the rear focal plane of the objective, is a suitable instrument for measuring thin films. The film is deposited, with a reasonably sharp edge, on a flat surface and covered with a reflecting metallic film, using, for example, silver or aluminium. The image of an illuminated slit, doubled by the Wollaston prism, is projected by the objective, via a prism type of vertical illuminator, normally on to the specimen. The reflected beams are polarized mutually at right angles and the path-difference between them is zero if both slit images fall either on to the substrate only or on to the film only. If one image falls on to the film and the other on to the substrate the path-difference is equal to twice the film thickness, and the problem becomes the polarimetric one of measuring this path-difference.

A suitable form of compensator for performing this measurement has been described[1], together with a visual half-shade device for making the settings and an optical device for translating the slit images across the specimen. However, as the visual method is found to be very fatiguing under the conditions imposed by the microscope, a photo-electric method was sought.

A satisfactory method has been developed using the electro-optical effect in ammonium dihydrogen phosphate[2]. The slit image formed in the image plane of the microscope passes through a plate of ammonium dihydrogen phosphate, cut normal to the optic axis and provided with transparent electrodes, then through an analyser and into a photo-multiplier. An a.c. voltage is applied between the electrodes. It can then be shown that the photo-multiplier output contains a component of frequency equal to that of the a.c. which is zero only when the path-difference between the two component beams is a whole number of half-wave-lengths. This fundamental component is detected by a phase-conscious rectifier which feeds a centre-zero meter. The setting operation then merely consists of operating the compensator until the meter reads zero.

By this means it has been found possible to make settings with a standard deviation corresponding to an uncertainty in film thickness of only 0·1 Å. The uncertainty is due largely to air currents, although the two beams are separated by only 0·2 mm.

This degree of accuracy is, of course, largely academic, as it is unlikely that a substrate as flat as this over 0·5 mm or so can be found. However, it is clear that settings to 1 Å unit can be made with certainty.

I thank Dr. T. E. Allibone, director of the Laboratory, for permission to publish this article.

MINERALOGY

Paragonite from the Dalradian

Two muscovite-rich red phyllites, one of chemical composition (per cent): SiO_2 59·6, TiO_2 0·9, Al_2O_3 18·1, Fe_2O_3 3·4, FeO 4·6, MnO 0·1, MgO 3·4, CaO 0·2, Na_2O 0·9, K_2O 4·7, H_2O 3·4, P_2O_5 0·2, CO_2 nil, total 99·5, carry a quartz–paragonite–muscovite–chlorite–hæmatite–rutile–apatite mineral assemblage. They come from the Dunoon phyllite, a low-grade horizon of the Dalradian, ¼ and ¾ mile north along the coast from Dunoon, Argyllshire. This is the first recorded appearance of paragonite as a rock-forming mineral from the Scottish metamorphic rocks, and its appearance elsewhere in low-grade rocks without albite is considered likely.

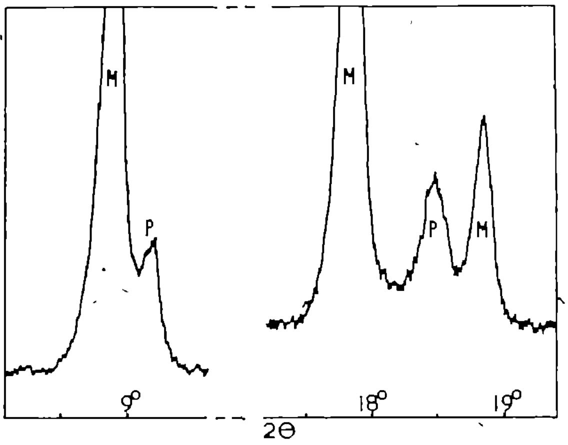

Fig. 1

The basal spacings of the co-existing muscovite and paragonite, calculated from the 002 peaks on a diffractometer trace, are 9·946 Å and 9·612 Å, respectively. Rosenfeld *et al.*[1] report the basal spacings of co-existing muscovite and paragonite from two biotite zone rocks to be: (1) 9·981 Å and 9·623 Å; (2) 9·975 Å and 9·623 Å. Paragonite is about 5 per cent of the total white mica. The diffractometer traces over the 001 and 002 peaks using copper *K* radiation are reproduced in Fig. 1.

CRYSTALLOGRAPHY

Molecular Structure of Tutin

TUTIN ($C_{15}H_{18}O_6$) was first isolated by Easterfield and Aston[1] and identified as the convulsive poison present in the leaves and seeds of the New Zealand species of *Coriaria*, a shrub known by the Maori as 'toi toi'. The molecular structure of tutin is now inferred from an X-ray crystal structure analysis of α-bromo-iso-tutin.

Tutin is one of a series of chemically and pharmacologically similar compounds of which picrotoxinin ($C_{15}H_{16}O_6$)[2,3] and coriamyrtin ($C_{15}H_{18}O_5$)[4] have been most intensively studied. The structure (I) for picrotoxinin was proposed by Conroy[5,6] and this was confirmed by X-ray crystallographic studies which also determined the absolute configuration of the molecule[7,8]. On the basis of the picrotoxinin structure and chemical degradation studies, Karyone and Okuda proposed structures (II) and (III) for coriamyrtin and tutin[4] respectively. Further chemical evidence[9] led to the dilactone structure (IV) for tutin proposed by Johns and Markham.

The crystal structures of four bromo-derivatives have been examined in order to determine their suitability for complete structure analysis by the heavy atom method. The crystal data for these compounds are given in

Table 1

Compound	Formula	Crystal system	a (Å)	b (Å)	c (Å)	d_{obs} g/cm³	$d_{x\text{-}ray}$ g/cm³	Z	Space group	x_{Br}	y_{Br}	z_{Br}
α_1-Bromotutin	$C_{15}H_{17}O_6Br$	Orthorhombic	7·28	8·77	23·31	1·67	1·67	4	$P2_12_12_1$	—	0·25	0·125

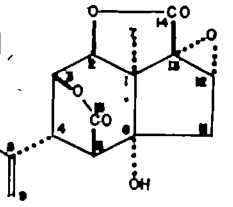
Table 1. Lattice parameters were measured from Weissenberg photographs taken with copper K radiation and the crystal densities were measured by the method of flotation in a mixture of bromoform and carbon tetrachloride.

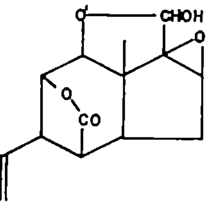
The two crystalline modifications α_1-bromotutin and α_2-bromotutin, here reported for the first time, are presumably analogous to α_1- and α_2-bromopicrotoxinin[10]. Although not required by space group symmetry, the bromine atom positions, as determined from Patterson projections, were found to be approximately at $y = 1/4$ in both the α_1- and α_2-bromotutin structures. This would complicate a structure analysis by introducing spurious symmetry into Fourier syntheses of electron density with the bromine atoms used as phase-determiners. A three-dimensional structure analysis of α-bromo-iso-tutin, rather than α-bromotutinone, was undertaken because of the uncommon trigonal crystal symmetry of the former structure.

Complete three-dimensional intensity data (1,988 non-symmetry-related reflexions) were recorded on Weissenberg multi-films and the intensities were estimated visually. The bromine atom position was deduced from sections of the three-dimensional Patterson synthesis, and the first three-dimensional Fourier synthesis with bromine phases clearly revealed the positions of all the carbon and oxygen atoms (Fig. 1). Although normally it is difficult at this stage of an analysis to distinguish between oxygen and carbon atoms from the peak densities in the approximate electron density maps, the configuration in the exo epoxy ring was evident from the formation of an intermolecular hydrogen bond of length 2·7 Å from the hydroxyl at C_2 to the epoxy oxygen. Structure factors calculated for all reflexions with an overall temperature factor of 2·5 Å² gave an R factor of 0·28. After two cycles of full matrix least-squares refinement with individual isotropic atomic temperature factors, R was reduced to 0·18. The refinement is being continued.

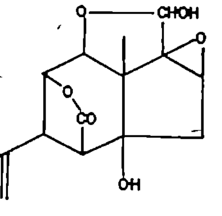
I



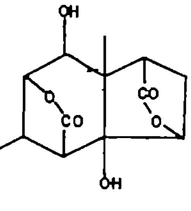
II



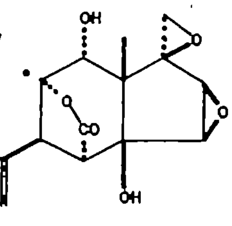
III



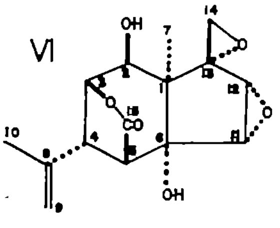
IV



V



VI



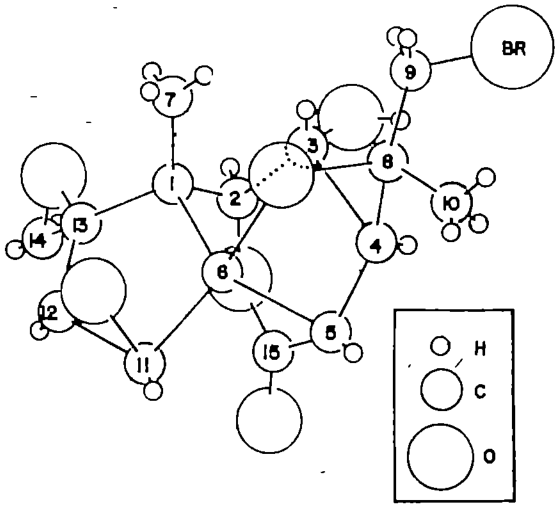


Fig. 1

If, as chemical evidence suggests, the tutin series differs from the iso-tutin series only in that the lactone ring closes at the C_3 hydroxyl, rather than the C_5 hydroxyl, then tutin has the structure (V) or its mirror image (VI). The absolute configuration of the molecule has not yet been determined, but by analogy with the absolute configuration of picrotoxinin[8], this may well be (VI). As in the case of picrotoxinin, the molecule features a framework of interlocking rings in a conformation which has complicated the determination of its structure from chemical and spectral evidence. Thus, in the iso-tutin series, the lactone grouping and C_2 and C_5 with their attached hydrogens shield the two epoxy rings, particularly the 11, 12 ring, from rearward nucleophilic attack.

This work was supported by grant B-3742 from the U.S. Public Health Service, National Institutes of Health.

Note added in proof. A crystal structure analysis of α-bromo-isotutinone by MacKay and Mathieson (C.S.I.R.O., Melbourne, Australia), which is in progress, confirms the molecular framework as reported here.

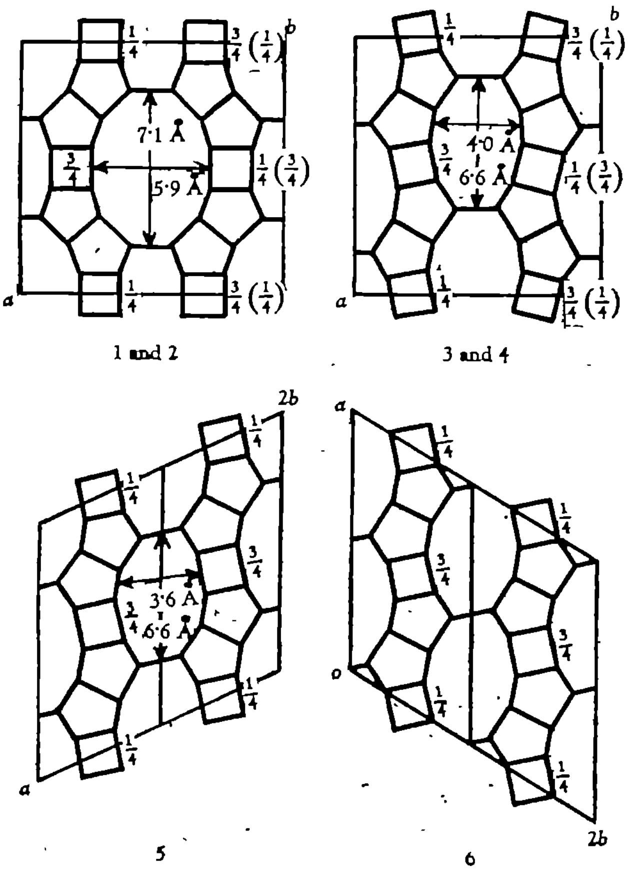
Possible Structures related to Mordenite

Meier[1] has recently given a structure for the fibrous aluminosilicate mordenite, containing strongly bonded chains of SiO_4 or AlO_4 tetrahedra. The chains, which have the unusual feature of containing a proportion of five-membered rings, are linked laterally to form a three-dimensional framework. All apical oxygen atoms are shared between two tetrahedra. In addition Meier and Gottardi[2] have shown that an alternative-side linking of the same chains can account for the structure of dachiardite. This raises the question whether there are more structures which can be built from these chains. A little consideration will show that there is, in fact, an endless number. However, some arrangements involve rather improbable linkings and result in large unit cells, while others can be obtained only by distorting the natural bonding distances within the chains. If both these types are omitted there are just six structures which have undistorted chains and unit cells not encompassing more than four chains.



1 and 2 3 and 4

5 6

Fig. 1. The six simple structures based on the mordenite-type chain. The numbers 1–6 correspond with those in the first column of Table 1. Heights of the four-membered rings are indicated, and for structures (2) and (4) the figures in parentheses must be read for the layer on the right. Approximate free diameters for the large channels are given

Fig. 1 shows the six structures projected down the axis of the chains with the unit cells thinly outlined. The choice of axes is kept as in mordenite, for both orthorhombic and monoclinic structures. *a* and *b* lie in the plane of the paper and *c*—the fibre axis—is perpendicular to this plane. Silicon (or aluminium) atoms are centred on corners while oxygen positions fall roughly halfway along each line. The mordenite chains (running normal to the plane of the paper) can be thought of as bonded together at intervals of $\frac{1}{2}c$ by the square four-membered rings, thus forming layers parallel to *ac*. These may then link together in one of two ways, in which a translation of $\frac{1}{2}c$ by alternate layers produces the second arrangement from the first. To show this the heights of the four-membered rings are indicated, choosing the origin as in mordenite.

In Table 1 the six arrangements are listed with their highest possible centric symmetries. The axes given are those found by calculation based on the mordenite cell. For dachiardite they compared with $a = 18{\cdot}73$, $b = 10{\cdot}30$ Å, $\gamma = 107°\ 54'$ for the natural mineral[3]; the *c*-axis, which is the chain repeat distance, equals 7·52 Å for each structure.

Table 1

No.	Structure Occurrence	Highest symmetry	*a* (Å)	*b* (Å)	γ
1	Mordenite	*Cmcm*	18·13	20·5	—
2	Unknown	*Immm*	18·13	20·5	—
3	Unknown	*Bmmb*	18·7	19·6	—
4	Unknown	*Bmmm*	18·7	19·6	—
5	Dachiardite	*B2/m*	18·7	10·3	106° 45′
6	Unknown	*B2/m*	18·7	11·7	123°

Only two of these structures occur in Nature, but a few crystals giving electron diffraction patterns corresponding approximately to the body-centred structure No. 2 have been synthesized hydrothermally from aluminosilicate gels containing strontium[4], similar to those gels which yielded a strontium-mordenite.

CHEMISTRY

Breaking Foams produced by Ionic Surfactants

A NEW and remarkably effective way of breaking foams produced by ionic surfactants has been discovered. In this connexion, it is necessary to distinguish between 'foams', which term, I suggest, be restricted to those systems stabilized by soluble surfactants at the air-water interface, and 'froths' which are stabilized by insoluble products at the air-water interface. When foams collapse, therefore, there is no visible residue whereas when froths collapse there is an insoluble scum produced.

If a temporarily stable foam produced using an anionic surfactant such as laurate or dodecylbenzenesulphonate has placed on it some foam produced using a surfactant of opposite charge, for example, trimethyldodecylammonium chloride, there is a dramatic interaction at those points where the two different foams meet, with mutual destruction. Furthermore, as foams are thermodynamically unstable, the quantity of the first foam destroyed by the addition of the second foam, which I propose calling a contra-foam, is very much greater than the amount of contra-foam added. For example, a vessel of 12-l. capacity was filled with a foam produced from dodecylbenzene-sulphonate. A blob of contra-foam, enough to cover a penny, was put on the top of the foam bed. Within a few seconds a cylinder, approximately of the diameter of the added contra-foam, was channelled right through the foam, leaving the remainder of the foam intact. Presumably the interaction takes place at the plateau borders, where the opposite charged surfactants meet and neutralize each other, but the instability, thus produced, proceeds some distance into the foam.

This is clearly due to opposite charge effects, because if foams produced from similarly charged surfactants or from non-ionic surfactants are contacted in the same way, there is no interaction at all, both foam and contra-foam remaining unchanged.

In a similar way, a foam produced from a cationic surfactant is quickly destroyed by using a contra-foam produced from an anionic surfactant.

By suitable placement of blobs of contra-foam, large amounts of foam can be made to collapse almost instantaneously using very little contra-foam. There is a slight residual scum, presumably produced as a reaction product between the oppositely charged surfactants, but the water substrate now shows no tendency to foam, showing that the surfactant from the collapsed foam does not re-enter the water in an active form.

In order to destroy an anionic foam it has been found that contra-foams produced from diamine surfactants are better than those produced from singly charged cationics, presumably because of the double charge. If the foam is simply sprayed with a dilute solution of the same contra-foam surfactant, the effect is not nearly so marked as when using a contra-foam itself. Presumably, the nature of foams is such that the opposite charges can get closer together more quickly if two foams are placed in juxtaposition.

For dealing with large masses of foam, a primitive foam gun was made. This consisted of a sintered glass porous plate fused into a 1·5 in. glass tube, which, about 6 in. above the porous plate, was bent to make an angle of 60°. A dilute solution of contra-foam surfactant is placed in the gun, bubbles generated by introducing compressed air, and using this, the contra-foam can be strategically directed so as to break the foam completely. In this way, it was possible, in a few minutes, to destroy completely a foam, which filled an open box, about 8 ft. cube. This foam was produced by a sewage effluent, and was probably due to the presence of dodecylbenzenesulphonate.

It is suggested that a method such as this might offer a means of dealing with some case of the nuisance foams produced by the so-called hard detergents. It should be emphasized that, so far, this method has only proved effective for dealing with foams, and not with froths, and quite obviously it has no use for breaking foams produced by non-ionic surfactants.

Ion-Exchange Theory of Coagulation

RECENTLY, Mirnik[1] has proposed a "mass-action law" theory of colloid stability, as an alternative to the Derjaguin – Landau – Verwey – Overbeek theory, lately extended by one of us[2]. The purpose of this communication is to examine the validity of Mirnik's arguments and of his experimental evidence. We shall summarize his basic assumptions using simplified notation as follows.

(1) A coagulating adsorbed counter-ion (cation) M', of valency z', associates with z' stabilizing (potential-determining) univalent anions A (I^- in the case of negative silver iodide) to form a molecular unit on the surface of a negative colloidal particle. If the chemical potentials (per mole) of the molecule, anion and cation are $\mu_{AM'}$, μ_A and $\mu_{M'}$ respectively, then the mass-action law reads:

$$\mu_{AM'} = z'\mu_A + \mu_{M'} \qquad (1)$$

If, in the solution phase, $\mu^{\circ}_{M'}$ is the standard chemical potential and c' the concentration of the cation in mol./l. and the activity coefficient is equated to unity, then $\mu_{M'} = \mu^{\circ}_{M'} + RT\ln c'$. Further, if γ is the maximum concentration of cations in the adsorbed state and $(1-x)\gamma$ the actual concentration where x is a fraction, then Mirnik assumes that $\mu_{AM'} = \mu^{\circ}_{AM'} + RT\ln(1-x)\gamma$, where $\mu^{\circ}_{AM'}$ is the corresponding standard chemical potential and again the activity coefficient is put equal to one. Substituting into (1), we obtain Mirnik's relation:

$$\ln c' = -z'a + \ln(1-x)\gamma - \ln D'_0 \qquad (2)$$

where

$$\ln D'_0 = (\mu^{\circ}_{M'} - \mu^{\circ}_{AM'})/RT,\ a = \mu_A/RT \qquad (3)$$

This is essentially a Freundlich adsorption isotherm for the counter-ion M'. (Mirnik expresses his concentrations in g. equiv./l., in which case c' and γ should be multiplied by z', but this does not change the final form (2).) Packter[3] has also applied the mass-action law to ion-pair formation on the particle surface, although between a counter-ion and only one stabilizing ion. However, he has incorporated this into the Derjaguin–Landau–Verwey–Overbeek theory.

(2) According to experimental work by Herak and Mirnik[4,5], two counter-ions (for example, Co^{2+} and Eu^{3+}) can exchange on the surface of the silver iodide particles and the total amount of adsorbed ions in g equivalents remains constant. If equations (1)–(3) refer to one ion species and a double dash is used to denote the other, then the relations corresponding to (2) and (3) for the second species read:

$$\ln c'' = -z''a + \ln x\gamma - \ln D''_0 \qquad (4)$$

$$\ln D''_0 = (\mu^{\circ}_{M''} - \mu^{\circ}_{AM''})/RT \qquad (5)$$

From their experiments, Mirnik and Herak[5] propose the relation:

$$\ln c'/c'' = (z'' - z')a + \ln[(1-x)/x] \qquad (6)$$

where a is practically independent of the concentration of stabilizing ion in the solution. In order that (6) be consistent with (2) and (4) it is necessary that $D''_0 = D'_0$ although the standard chemical potentials in the expressions for D''_0 and D'_0 refer to different species. Furthermore, the constancy of a implies that the chemical potential of ion A in the solution is independent of its concentration whereas, for negative silver iodide sols, the variation in a is $\Delta a = \Delta\mu_A/RT = -2{\cdot}3\,\Delta pI$, where pI can vary from 1 to 7. Thus Mirnik's deductions cannot be valid, and we must conclude that at least one of the relations (2), (4) and (6) is incorrect. Mirnik apparently avoids the anomaly of fixed μ_A by postulating that the chemical potential of a stabilizing ion in the adsorbed state differs from that of the same ion in the solution phase, but this contradicts thermodynamics.

If $x = 1/2$ and $z'' = z'$ then on a $\ln c' - \ln c''$ plot the relation (6) represents a straight line having a slope of 45° and passing through the origin. However, an examination of Herak and Mirnik's work (Fig. 8, ref. 5) shows that the ion-pairs $Y^{3+} - La^{3+}$ and $Y^{3+} - Nd^{3+}$ give two lines of somewhat different slopes, although the authors have drawn a common line for the two. Neither of these two lines goes through the origin. This means that D'_0 differs from D''_0 even though the two ions M' and M'' have the same valency ($\ln(D'_0/D''_0) \sim 1$ for the pair $Nd^{3+} - La^{3+}$) and we may expect a greater difference with ions of different valencies. Also, the experimental results summarized in Tables 1 and 2 of the same work[5] show a spread in the values of a which cannot be neglected.

(3) The experiments of Mirnik and Herak cast doubt on the relations (2) and (4) in another way. Mirnik postulates a hypothetical adsorbable uncharged species exchanging with ion M''. If c_0 is the concentration of this species in the liquid phase and $(1-x)\gamma$ its concentration in the adsorbed phase, then in place of (6) we have:

$$\ln c''/c_0 = -z''a + \ln[x/(1-x)] \qquad (7)$$

This relation can also be regarded as an adsorption isotherm for counter-ion M' provided c_0 is known. The experimental adsorption isotherm for Eu^{3+} by Mirnik and Herak[6] resembles the Langmuir rather than the Freundlich adsorption law. In explaining this, they assume that c_0 is independent of x, in contradiction to (2), and consequently introduce two different forms for the same quantity c'' as a function of x. In earlier work, Težak[7] had already introduced the uncharged species and assumed that the concentration c_0 was so much greater than c'' that it could be regarded as constant.

(4) Perhaps the most controversial conjecture of Mirnik is that a water molecule forms a complex with two stabilizing anions (one for each hydrogen) and stabilizes the colloidal particle. This complex is treated in the same way as the species AM'; it has a concentration $(1-x)\gamma$ in

the adsorbed state and can interchange with the molecule AM'', where M'' is the coagulating ion. If $\mu_{(A,\,H_2O)}$ is the chemical potential of this negative ion complex of valency 2, $\mu^0_{(A,\,H_2O)}$ the corresponding standard chemical potential and μ_{H_2O} the chemical potential of water, then according to Mirnik:

$$\mu_{(A,\,H_2O)} = 2\mu_A + \mu_{H_2O} = \mu^0_{(A,\,H_2O)} + RT\ln(1-x)\gamma \qquad (8)$$

Mirnik's basic hypothesis is that the coagulation condition is given by:

$$\mu_{(A,\,H_2O)} = \mu_{AM''}(= \mu^0_{AM''} + RT\ln x\gamma) \qquad (9)$$

Making use of (8) μ_A is replaced by $(\mu_{(A,\,H_2O)} - \mu_{H_2O})/2$ in (5) and the relation (4) yields

$$\ln c''_{\text{coag}} = -z''a + \ln x_{\text{coag}}\gamma/D''_0 \qquad (10)$$

for the coagulation concentration c''_{coag}. Mirnik also assumes that $\mu^0_{(A,\,H_2O)} = \mu^0_{AM''}$, thereby again equating standard chemical potentials of different species, and therefore derives from (8) and (9) the curious result that at critical coagulation $x = x_{\text{coag}} = 0{\cdot}5$. If a is independent of the concentration of stabilizing ion (which we have shown to be incorrect) and both x_{coag} and D''_0 are independent of the valency z'', then (10) is a linear relation between $\ln c''_{\text{coag}}$ and the valency z'' of the coagulating ion. Mirnik interprets this as the Schulze–Hardy rule.

It seems that there cannot be a mathematically simple Schulze–Hardy rule which applies to sols in general[3]. Indeed, there are examples which follow other formulations, for example, for arsenic sulphide sols, $\ln c''_{\text{coag}} =$ constant $- 6\ln z''$ seems to be a good approximation. Ion exchange usually applies to two ions of the same sign whereas in Mirnik's theory the counter-ions exchange with electrically neutral water molecules. In this connexion, if the criterion (9) were acceptable, it would be more logical to express it in gram equivalents, so that the same numbers of stabilizing ions are neutralized in the exchange process. Hence this criterion should read $z''\mu_{(A,\,H_2O)} = 2\mu_{AM''}$ (so that $2\mu_{M''} = z''\mu_{H_2O}$). The determination of x_{coag} from this relation becomes uncertain because of the term $RT\ln\gamma$ and in general x_{coag} would depend on z''. There seems no physical justification for the value $x_{\text{coag}} = 0{\cdot}5$, and indeed Mirnik and Herak cannot fit their theoretical adsorption isotherm to their experimental one[6]. Furthermore, their theory does not explain how the water molecules can be stabilizing agents for both negative and positive sols.

As experimental evidence for their Schulze–Hardy rule Herak and Mirnik claim that the plots of "valency-logarithm coagulation value" and "valency-logarithm desorption concentration" at $x = 0{\cdot}5$ are parallel (Fig. 4, ref. 4). However, this does not follow from the example given by the authors because their coagulation concentrations (c_{coag}) of Na^+, La^{3+} and Th^{4+} appear to be in error. The value for Na^+ is too low and that for La^{3+} too high[8]. Indeed, Herak and Mirnik's own value of c_{coag} for Nd^{3+} is much lower (Fig. 5, ref. 4) and one would expect this to be very similar to the true c_{coag} for La^{3+}. Finally, as plotted, c_{coag} for Th^{4+} is also too high, which is probably due to the high pH at which the ions are hydrolysed giving species of lower valency. Thorium exists in solution as an ion of charge $+4$ only at $p\text{H} < 4$ (ref. 9), where its c_{coag} is lower than the value used by Herak and Mirnik. If the correct values of c_{coag} of all these ions are used, the "valency-logarithm coagulation value" line has a smaller slope than the "valency-logarithm desorption concentration" line, the ratio of the slopes being about 0·6, contrary to Mirnik's theory.

This theory is presented as an alternative to the widely accepted theory that colloid stability results from an interplay of electric double layer repulsion and van der Waals attraction between colloidal particles. In our opinion there is no reason why Mirnik's theory should be accepted as correct.

One of us (S. L.) is indebted to Prof. Mirnik for helpful discussions and communications. This work was supported in part by a grant from the U.S. Army Research Office No. *DA–ORD*–10.

Ionization by Charge Transfer of Adsorbed Gases in Mass Spectrometers

IN a recent investigation of anomalies in the ionization of different simple gases by mono-energetic electrons Marmet and Morrison[1] pointed out that charge exchange occurs in the ionization chamber of a mass spectrometer operating at low pressure, and therefore should be occurring on the walls. Investigating the ionization of nitrogen, they observed that an addition of water in the gas stream brought indeed a reduction of about 1·5 V in the appearance potential of N_2^+ ions, observed at about 14·1 V, whereas the normal first ionization potential of nitrogen is 15·58 V. They ascribed this result to a reaction such as:

$$N_2^* + H_2O^+ \rightarrow N_2^+ + H_2O \qquad (1)$$

On the other hand, recent shock-wave experiments on energy transfer by Clouston *et al.*[2] and sound propagation studies by Parbrook and Tempest[3] show that the cross-section for deactivation of vibrationally excited nitrogen is 10–100 times more effective in water–nitrogen collisions than in nitrogen–nitrogen collisions, suggesting that interactions between nitrogen and water molecules are highly probable as soon as the chance for them to meet within narrow distances is high enough. The studies show also that relaxation times for vibration are of the order of 10^{-4}–10^{-7} sec.

Lindholm[4] showed that the cross-section for charge exchange in ion impact phenomena is high if the energy required for ionization is close to the recombination energy of a given ionic state of the ion which takes up an electron.

Therefore we suggest that the reaction (1) be more accurately written in the following way:

$$N_2^* + H_2O^+(^2A_1) \rightarrow N_2^+(X^2\Sigma_g^+) + H_2O \qquad (2)$$

since the ionization potentials of water are 12·60 V ($^2B_1$), 14·35 V ($^2A_1$) and 16·34 V ($^2B_2$), as determined by Frost and McDowell[5], and an examination of Fig. 10 of ref. 1 shows the uncertainty is such that the appearance potential of N_2^+ might be as high as 14·5 V (corrected).

This of course does not explain why the appearance potential of nitrogen is so much reduced. Marmet and Morrison suggested that it is due to adsorption of nitrogen. Investigations on photoelectric effects of adsorption phenomena have indeed shown that the lowering of the ionization potential of the adsorbed species is not unfrequent, but the effect is much less important, being of the order of a tenth of a volt[6], than the one referred to here. Moreover, the adsorption of normal nitrogen molecules on a metal surface at 400° K should not be very important, particularly at pressures as low as 10^{-5}–10^{-6} mm.

For these reasons, we would prefer to think that a vibrational or electronic excitation of the nitrogen molecule takes place in the gas phase, by inelastic collisions with electrons, prior to adsorption. The vibrational quantum of nitrogen being 0·29 V (= 2,359 cm⁻¹) one should admit the molecules are in their 3rd or 4th vibrational level, the thermal energy being only about 0·04 V. A possible process for this vibrational excitation is the formation of a negative transitory N_2^- ion, loosing its electron and afterwards getting vibrationally excited. This may occur in the particular case of nitrogen as has been shown by Schulz[7].

The other possibility is an electronic excitation by the electron beam; this happens for higher electron energies, and Schulz[7] has distinguished the formation of $A^3\Sigma_u^+$, $a\,\Pi_g$ and $C^3\Pi_u$ excited states at approximately 8, 10 and 12 V. There is no way for the moment of deciding what state might be concerned here, but it may be pointed out that the first excited electronic states of nitrogen correspond to an electron jump into either a $\pi_y^*\,2p$, a $\pi_z^*\,2p$ or a σ^*2p orbital; these are all antibonding and should bring an increase of nuclear distance, resulting in a more polarizable and more easily adsorbed molecule.

Finally, the curve reported by Marmet and Morrison shows a hump about 1·2 V above threshold and it may be significant that the first excited state $A^2\Pi_u$ of the N_2^+ ion is also situated some 1·15–1·21 V above the ground $X^2\Sigma_g^+$ state[8].

To conclude, the anomalies observed may be explained on the assumption of excited states of ions taking part in the charge exchange process on the surface, after vibrational or electronic excitation of the nitrogen molecule in the gas phase by electron collisions. Experiments of charge exchange between nitrogen and water by Lindholm's ion bombardment technique should also prove useful in explaining these phenomena.

Luminescence from the H—O₂ Reaction

THE spectrum of the HO_2 radical is of considerable importance and several unsuccessful attempts have been made to record it. The HO_2 radical has one more electron than the HNO molecule, which has an electronic transition at 7600 Å (ref. 1), and consideration of the molecular orbitals of HO_2 suggests that this radical should have a very similar electronic transition to that of HNO (ref. 2). The HNO spectrum was first obtained in absorption during flash photolysis experiments[1], but has more recently been observed in emission in the chemiluminescent reaction of hydrogen atoms with NO (ref. 3). The similarity of the bond dissociation energies of H—NO (49 kcal/mole)[3] and H—O_2 (46 kcal/mole)[4] suggests that hydrogen atoms might give a chemiluminescent reaction with oxygen, despite previous failures to find any electronic emission from this reaction.

Hydrogen atoms were produced by the dissociation of commercial hydrogen in two Wood's tubes and pumped through two side-arms on opposite sides of a reaction vessel 3·5 cm in diameter and 35 cm long connected directly to a 150 l./min rotary pump. Commercial oxygen was introduced through a third side-arm situated between the hydrogen inlets. The vessel was screened from direct light from the discharges, and mounted end-on directly in front of the slit of a Hilger 'Wave-length' spectrograph with *f*/10 glass optics and a focal length of 30 cm. The spectrum shown in Fig. 1 was photographed on hypersensitized Kodak II.*N* (I.R.E.R.) plates in 30 min, using a 100μ slit-width, and a partial pressure of each reactant of about 0·5 mm mercury. No visible glow was apparent. The intensity of the spectrum was extremely variable, and the relative intensity of hydrogen and oxygen atomic lines, due to partial entry of the discharge region into the reaction vessel, was also very variable, as shown by the comparison between the spectra in Fig. 1*a* and *b*, which were taken under almost identical conditions. However, the intensity distribution within the spectrum was reproducible. The erratic behaviour suggests that a trace impurity may be important in the production of the spectrum, either because the impurity supplies the excited molecules, or because the impurity (water ?) acts as a catalyst in the production of the excited molecules.

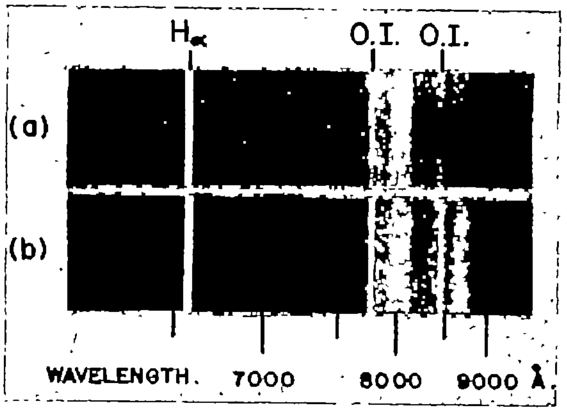

Fig. 1. The spectrum emitted in the reaction of hydrogen atoms with oxygen

The reaction between hydrogen atoms and ozone leads to the emission of near infra-red vibration-rotation bands of OH (ref. 5), and H_2O emits near infra-red vibration-rotation bands in the flame of oxygen burning in an atmosphere of hydrogen[6]. However, both these systems are of red-degraded bands, and their wave-lengths do not agree with those of the spectrum in Fig. 1, which shows prominent violet-degraded heads at 6853, 7149, 7562 and 8103 Å (± 10 Å). The coarse rotational structure of the HNO bands is violet degraded, due to an opening out of the HNO angle on electronic excitation, and a similar behaviour is to be expected for HO_2. Thus, although there is no proof of the carrier of the observed spectrum, it seems possible that this is the spectrum of the HO_2 radical.

A new reaction vessel is being built to accommodate a set of multiple reflexion mirrors, and it is hoped to obtain sufficient intensity for a higher resolution study of this spectrum.

Measurement of Small Quantities of Calcium by Radiometric Precipitation

Radiometric precipitation is in principle an extremely sensitive method of analysis, but in practice the sensitivity is usually limited by the efficiency of separation of the precipitate and its parent solution[1,2]. An adaptation of the technique of chromatography affords a quick and simple method both of phase separation and of washing the precipitate with a small volume of liquid. I have used this method to measure concentrations of calcium as low as 10 p.p.m. in less than 1 mg of solution.

In this method equal quantities of nitric acid containing the calcium sample and of 1 per cent fluoride solution labelled with radiofluorine are measured in a length of fine bore polythene tubing attached to a microsyringe and then mixed and temporarily stored in a small polythene bubble. The solution is then spotted on a strip of chromatographic paper where calcium fluoride is precipitated when its *p*H is raised by blowing on ammonia. This method of raising the *p*H is much to be preferred to that of adding liquid as the latter tends to move the solution without mixing well with it. After precipitation some 1,000 p.p.m. fluoride solution is allowed to run along the paper until the excess activity has moved away from the precipitate, which remains stationary. A fluoride solution has to be used for the irrigation, rather than water, as about 10^{-3} ml. runs through the precipitate and this quantity of water would dissolve 10^{-7} g of calcium from calcium fluoride. Finally the paper is dried and the piece containing the precipitate is cut off so that the activity of the precipitate can be measured.

The quantity of calcium in an unknown sample must be determined from a calibration curve of standard calcium samples (Fig. 1) because, although the activity is directly proportional to the calcium concentration over a range of several hundredfold, the measured activities of precipitates from standard calcium solutions containing 1 per cent of fluoride are roughly half of those expected on the grounds of chemical equivalence and the known specific activity of the fluoride. Some of the activity is lost by exchange of fluoride during the irrigation and some of the calcium is precipitated as calcium hydroxide when the *p*H rises abruptly. The first reaction causes only a uniform reduction in the activities of a set of precipitates, as would the second if the rate of absorption of ammonia were the same for each sample. However, random variations in the quantity of fluoride precipitated with calcium are reduced to about 5 per cent if phosphoric acid, a powerful buffering agent, is present in the solution at a level of a few per cent. The precipitate with buffer is again a mixture, as the phosphates of calcium are only slightly soluble, but its composition will be determined mainly by the ratio of fluoride and phosphate concentrations. Further, at this level phosphoric acid has the advantage of swamping the effect of any phosphate in the unknown calcium samples.

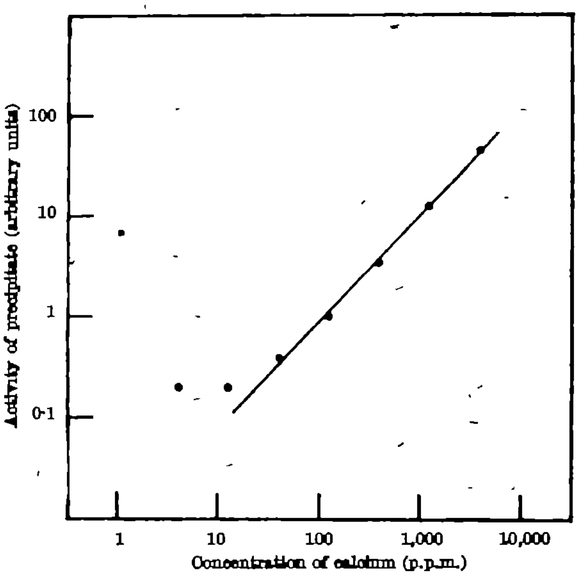

Fig. 1. Labelled fluoride precipitated with calcium

Any substance which is present in the unknown sample and is capable of forming an insoluble compound with either calcium or fluoride might, in principle, interfere with this method of analysis. However, small quantities of anions can be masked in the way described here for phosphate: by the addition of a larger quantity of the interfering anion to all the calcium solutions so that the precipitate is a mixture of constant composition. Interference by substances with fluorides of low solubility is troublesome; the effect of magnesium, for example, is complex and if it is present at a level of more than one-tenth of the calcium concentration the method is unreliable.

Before use the chromatographic paper must be washed in a dilute solution of either ethylenediamine tetraacetic acid or hydrochloric acid to remove a background contamination which is probably calcium. Even so, traces of fluoride stick to the paper limiting the sensitivity of the analysis. Solutions containing less than 10 p.p.m. of calcium, the level at which the activity of the precipitate is comparable with the background activity left in the paper, must be concentrated. This can be done without risk of contamination by freezing the solution in an unsealed polythene bubble and then drying under vacuum.

The principle of this method should be widely applicable; the main limitations being probably in handling small quantities of liquid and in finding suitable chromatographic paper.

I thank Mr. I. N. Tully for his help in the development of this technique.

Phosphorescence in Plastics

A recent communication from Oster *et al.*[1] reported their finding of room-temperature phosphorescence in plastics containing dissolved aromatic hydrocarbons or dyes.

We wish to direct attention to work in the laboratories of the General Post Office Engineering Research Station in 1957 and onwards which resulted in the preparation of phosphorescent plastics having long decay times at room temperature. The work has been referred to elsewhere[2] but has not hitherto been described in the chemical literature and may be of interest to those engaged in the examination of luminescence processes.

In a search for cheapened forms of phosphors suitable for mail-coding applications, various organic systems were examined. It was found that enhanced intensities and prolonged decay periods were given at room temperatures when certain types of activating molecule were reacted simultaneously with the major components of aminoplastic resins. Since the resins formed from cyanuric acid and formaldehyde were more easily ground to a fine powder (suitable for use in printing inks, etc.), most of the results were obtained with this system. The amino-resin phosphors have been patented[3], and two such powders have been successfully used in field trials of automatic mail facing and sorting.

We find that the most effective activators contain one or more aromatic rings with substituent groups capable of reacting to form part of the resin molecule. Generally, —OH or —NH$_2$ groups are present but condensed ring hydrocarbons having active positions also give phosphors, though of lower activity. In all cases, the presence of —SO$_3$H groups augments the luminescence and shifts both the peak excitation and luminescence towards longer wave-lengths. Some of the phosphors exhibit luminescence which is visually detectable (in the dark) for up to 40 sec after ultra-violet irradiation. The greatly enhanced intensities and durations suggested that these systems might be qualitatively different from those previously reported. No detailed study has been made of the chemical or radiative processes involved, but some activators were structurally modified in an effort to establish if chemical linkage with the resin matrix were essential. The results indicate that this is so. Thus, cyanuric acid containing 1 per cent of *p*-hydroxy-diphenyl yields a formaldehyde-condensation product showing luminescence, in the range 4300–6300 Å, which is visually detectable for about 20 sec after irradiation at 2537 Å. If the *p*-hydroxydiphenyl is replaced by di-*p*-diphenyl ether or methyl-*p*-diphenyl ether there is no visually detectable delayed luminescence after irradiation with long- or short-wave ultra-violet light. Also, the phosphorescence imparted by *p*-phenylene diamine is slightly exceeded by that of the (nuclear substituted) 2,3,5,6-tetra-methyl derivative but no phosphorescence is observed if *N,N,N′,N′*-tetra methyl *p*-phenylene diamine is used. The blockage of the —OH and —NH$_2$ groups has in each case resulted in a drastic reduction of the phosphorescent properties, with no obvious change in the fluorescence.

The work is insufficient to justify firm conclusions, but it does seem probable that these materials differ qualitatively from the solutions which have been generally studied. Oster *et al.*[1] give some evidence for specific interactions between activating molecules and the polymeric matrix. It may be that the amino-resins provide an environment specially favourable to high phosphor efficiencies, even for dissolved species, but it also appears that the purely physical effects of a rigid matrix are here augmented by chemical bonding of the activating centres to the main network of the amino-resins.

We thank Mr. T. P. Stein for assistance in preparing structurally modified activators. We also thank the Engineer-in-Chief, General Post Office, for permission to publish this communication.

Acid Leaching of Uranium and Thorium Carbides

IN a recent communication by Sasaki *et al.*[1] attention is directed to the use of the carbides of uranium, plutonium and thorium as nuclear fuels and to the problems associated with processing and recovery of the irradiated fuel. It is revealed that in the acid leaching of thorium carbide (ThC$_2$) with nitric acid of concentrations below 4 N gaseous hydrocarbons are evolved, whereas at concentrations above 4 N organic material is produced, and evidence is presented that this organic matter does not have a C—H bond as indicated by the results of infra-red analysis. The formation of organic material during the acid leaching of uranium monocarbide has also been observed by Simpson *et al.*[2] and the presence of this could constitute a hazard in the uranium recovery process, although its formation may be avoided by prior hydrolysis of the carbide in water and subsequent dissolution of the resulting oxides in nitric acid[3].

We have examined the reaction of uranium monocarbide with nitric acid (6 N) and after removal of uranium from the resulting solution with tributyl phosphate in benzene[4] the aqueous raffinate was evaporated and the residue esterified with diazomethane. Chromatography of the mixed esters on alumina from benzene solution gave hexamethyl mellitate, which was identified by analysis and by comparison with an authentic specimen. Further elution of the column gave intractable resins. In one experiment involving the dissolution of uranium carbide in nitric acid (6 N) the solution was left for six weeks before processing and oxalic acid separated from the reaction mixture. An X-ray analysis of the uranium monocarbide utilized in the leaching process did not reveal the presence of free graphite and we suggest that the reaction proceeds by a breakdown of uranium carbide with formation of graphitic carbon which is then oxidized to oxalic and mellitic acids.

$$UC + 2O \rightarrow UO_2 + C$$

Mellitic acid was also isolated (as the hexamethyl ester) from the reaction of nitric acid (6 N) with uranium dicarbide (UC$_2$), uranium sesquicarbide (U$_2$C$_3$) and the carbides of thorium (ThC, ThC$_2$ and Th$_2$C$_3$).

In a typical experiment uranium monocarbide (519 g) and nitric acid (6 N; 4 litres) were allowed to react for twenty-six days and filtered from insoluble material. The aqueous filtrate was extracted until free of uranium with a 20 per cent solution of tributyl phosphate in benzene which had been equilibrated with nitric acid (6 N). Evaporation of the aqueous raffinate under reduced pressure gave a residue (12·7 g) which was suspended in ether and treated with an excess of ethereal diazomethane. Filtration from insoluble matter (24 g, containing 13·5 per cent of the initial carbon) and evaporation of the filtrate gave a mixture of esters (13 g) which was chromatographed on alumina from benzene solution. Elution with benzene furnished hexamethyl mellitate (5·1 g). Further elution of the column with ether, ether–methanol and methanol gave intractable mixtures. Approximately 30 per cent of the initial carbon was evolved as carbon dioxide during dissolution in nitric acid. Together with a 4·3 per cent yield of oxalic acid isolated in one case, the foregoing products account for 83 per cent of the carbon present initially. The optimum material balance (95 per cent) was secured in the case of uranium sesquicarbide, which afforded 38 per cent carbon dioxide, 10 per cent mellitic acid and 46 per cent other acids (unidentified: yield estimated as 'mellitic acid'). The corresponding yields for the other carbides were approximately: UC$_2$: 29, 8, 25; ThC: 47, 5, 23; ThC$_2$: 33, 3, 8 and Th$_2$C$_3$: 27, 1, 15 per cent.

We thank Mr. K. Hartley and Dr. G. Maclennan of the U.K. Atomic Energy Authority for directing our attention to the problem, Dr. H. B. Bell of the Royal College of Science and Technology for the X-ray analysis and Mr. T. Boyle for assistance. We also thank the U.K. Atomic Energy Authority for a grant and the supply of carbides.

BIOCHEMISTRY

Starch-gel Electrophoresis of Pig Serum Proteins

MANY variations of the original technique of Smithies[1] for starch-gel electrophoresis of proteins have been developed, notably the vertical gel[2], the discontinuous buffer system[3], and two-dimensional applications[4,5]. The latter method has been used by Ashton[6] in examining pig serum proteins; it has one disadvantage in being time-consuming, requiring two electrophoretic runs, and at the most only two samples can be compared at once on normal apparatus.

In the investigation of pig serum reported here a discontinuous buffer system was used in a vertical apparatus, which enables ten samples to be characterized during one day's operation, with a separation into 22–26 components. A 12 per cent gel made up in buffer consisting of 0·010 M boric acid and 0·006 M *tris*, *p*H 8·6 (at 5°), is poured into the ends of the apparatus and allowed to set before trimming off to leave a rectangular hollow, into which the second gel is poured. This is made up in 0·25 M sucrose, 0·0015 M citric acid, 0·020 M *tris*, *p*H 9·1 (at 5°). The slots are formed in this gel using a slot-former as described by Smithies[2]. Electrophoresis is carried out for 6 h at 300 V, 15–20 m.amp in a room kept at +1°. The gel temperature at the end of a run is usually about 5°.

Blood samples have been taken at slaughter (age approximately 6 months) and allowed to clot overnight before pouring off the serum and centrifuging to remove any red cells. Serum is stored at −20°, with no apparent deterioration in 6 months as observed on the starch gel.

Typical patterns are shown in Fig. 1, with a convenient nomenclature of the bands given in Fig. 2. Polymorphism in the pre-albumins, α-globulins and β-globulins[6] has been found, and no two sera have yet shown identical patterns. The chief β-globulin patterns (variations in bands *B2*, *B3* and *B4*) are shown in the first three samples, (*a*), (*b*) and (*c*), type (*a*) being the more common. Sample (*d*) shows an example of a serum as yet found only in one particular litter of Large White pigs, and sample (*e*) the only serum so far obtained from an Essex breed; in both of these band *B6* is lacking or only present to a comparatively small extent. Sample (*f*) is from an 8-week-old animal, in which it can be seen that the γ-globulins *G3–5* are not yet fully developed[7]. Differences between the main breeds (Large White, Landrace, Wessex, Welsh), if any, are very small, yet the genetic polymorphism results in patterns of quite different appearances within one litter. It is probable that a statistical analysis of the various patterns will show certain forms as being more common in one breed than in another, and similar correlations should be possible with other characteristics of the animals[8].

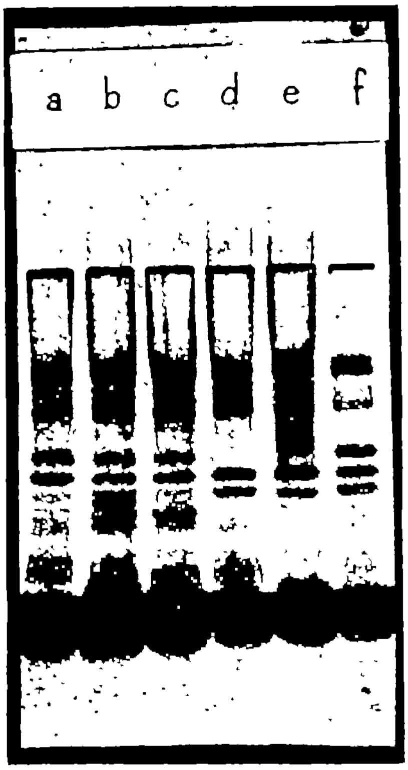

Fig. 1. Electrophoretic patterns of pig sera on starch-gel

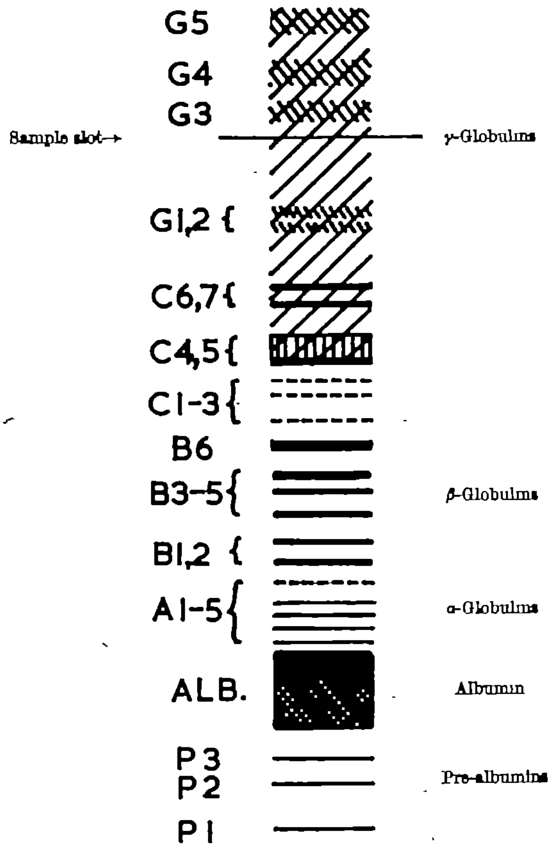

Fig. 2. Composite pattern of bands after electrophoresis, showing nomenclature used

Use of different buffer systems, for example, a triple discontinuity in the gel, results sometimes in better separations; with one system the albumin band has split into at least six components. But these methods are not always better for a complete comparison of all the protein bands, and so the system described here has been used for standard electrophoretic runs. Preliminary results with beef serum have yielded up to 36 bands using this standard method.

Post-mortem Lability of Skeletal Muscle Proteins

As a result of the post-mortem conversion of glycogen to lactic acid, the pH of skeletal muscle falls from its *in vivo* value of about 7·3 to about 5·5, the actual level attained depending on several factors, such as the physiological state of the animal before death, the type of muscle and the temperature during glycolysis[1,2]. It has recently been shown in pig muscle that, where the rate of pH fall is fast and a relatively low pH is therefore attained while the temperature is still high, there may be considerable denaturation and precipitation of sarcoplasmic proteins[3]. It is also well known in enzyme preparatory procedures that lowering of the pH of extracts from animal tissues precipitates particulate material and nucleoprotein[4].

Giles[5], Tsuyuki[6] and others have used vertical starch-gel electrophoresis to separate sarcoplasmic proteins of various species. These were extracted from muscles which in some cases had already attained a low pH, however; it is thus likely that certain components had been denatured, were not extracted and did not appear on subjecting the extracts to starch-gel electrophoresis. The present investigations, in which a similar technique was used, have clearly indicated that certain sarcoplasmic proteins are unstable *post mortem*; precipitation of even small amounts of these can inhibit the normal extraction behaviour of muscle protein fractions[3,7].

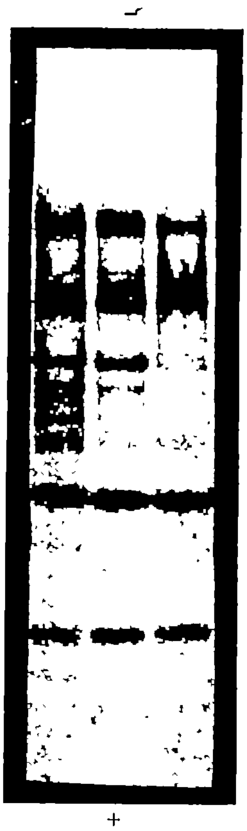

Fig. 2

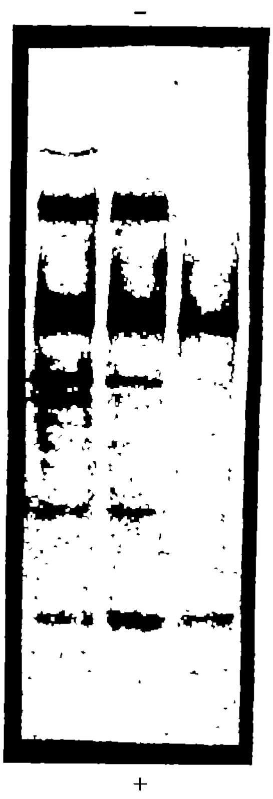

Fig. 3

Fig. 2. Electrophoretogram of beef muscle sarcoplasmic proteins. Left to right: extract of pre-rigor muscle; extract of muscle which was held at 0° for 20 h *post mortem*; extract of muscle which was held at 37° for 4 h *post mortem*

Fig. 3. Electrophoretogram of pig muscle sarcoplasmic protein. Left to right: (*a*) normal pig muscle; (*b*) 'white muscle disease' pig muscle; (*c*) severe 'white muscle disease' pig muscle

Beef l. dorsi muscle was obtained immediately after slaughter and had been chilled to 0° C. within 1 h of death. Samples were held at 0° C for 20 h, at 37° C for 4 h, or used at once. Homogenates were extracted with distilled water, after adjusting the pH to 7·0 with M *tris*, and the extracts were subjected to starch-gel electrophoresis. Some 35 bands can be obtained from beef muscle; these are diagrammatically represented in Fig. 1. In Fig. 2, it can be seen that several components are removed completely or very much diminished by the fast post-mortem glycolysis which occurs at 37° C in comparison either with the initial condition (before post-mortem glycolysis had proceeded appreciably) or with muscle in which post-mortem pH fall has been relatively slow (that is, at 0° C). Even in extracts prepared from muscles which have had a slow rate of pH fall, there are minor differences compared with those from the initial material of high pH, and it is evident that at the normal ultimate pH of muscle—5·5—certain sarcoplasmic proteins are already denatured and immobile.

Fig. 3 demonstrates that the major component of pig muscle sarcoplasmic proteins which migrates towards the anode at pH 8·5, and corresponds to a similar major component in electrophoretograms of beef muscle extract (arrowed in Fig. 1), and to band 9 in those of rabbit muscle (as tabulated by Hartshorne and Perry[8]), is markedly affected by the high-temperature/low pH combination. All these samples were prepared from post-rigor pig l. dorsi muscle; samples (*b*) and (*c*), however, were obtained from pigs having 'white muscle disease', in which the pH dropped rapidly *post mortem*, while the temperature was still high[8]. This caused considerable denaturation and insolubility of this sarcoplasmic component; some other proteins affected are also clearly demonstrated. Sample (b) shows some variation from the other two which may be attributable to breed differences.

Precipitation of the 'pH 5' proteins[9], by lowering the pH of sarcoplasmic extracts, produces a fraction which, on re-solution at pH 7·5, corresponds for the most part with the components most affected by the high-temperature treatment. It is concluded that *in situ* isoelectric precipitation of these proteins renders them more susceptible to heat denaturation. Most of them are still extractable on raising the pH to 7·0 providing that the temperature had not been high during the post-mortem pH fall.

Thus, it has been shown that several protein components of the sarcoplasmic complex are unstable and either denature, or are isoelectrically precipitated by the post-mortem pH fall in muscle, both if this is extensive (low ultimate pH) and/or fast. Many of the protein constituents are completely stable, however, and show no diminution in the starch-gel patterns, under these conditions.

This work was financed by the U.S. Department of Agriculture (grant No. *FG–UK*–101–59).

Note added in proof. The major component referred to (arrowed in Fig. 1) has been identified as creatine phosphoryltransferase in both pig and beef muscle. It is not, however, found in the 'pH 5' proteins.

Spectrophotometric Assay of Ascorbic Acid Oxidase

The method generally used for assay of ascorbic acid oxidase depends on the fact that, within a certain range of enzyme concentration, the rate of oxygen consumption during ascorbic acid oxidation is proportional to the amount of enzyme present[1]. Daglish[2] and Hewitt and Dickes[3] proposed the utilization of the ultra-violet absorption peak of ascorbic acid at 265 mμ as a quantitative measurement of ascorbic acid.

A utilization of the ultra-violet absorptive properties of ascorbic acid is proposed for measuring ascorbic acid oxidase activity spectrophotometrically at 265 mμ, by following the diminution of the absorption peak of the acid. Fig. 1 shows the spectra of 0·1 and 0·2 μmole of ascorbic acid in 3 ml. in a 1-cm cuvette (curves A and B respectively) and after enzymatic oxidation (curve C). The enzyme preparation alone gave the spectrum shown in curve D. From these results it can be seen that the decrease in absorption at 265 mμ can be adopted for determining the rate of enzymatic oxidation of ascorbic acid.

A Beckman *DK2* recording spectrophotometer equipped with a time drive was used in this work; however, a *DU* spectrophotometer may be used. Small oranges, *Citrus sinensis* (1–3 cm diam.), were found to be high in ascorbic acid oxidase and were used as a source of the enzyme.

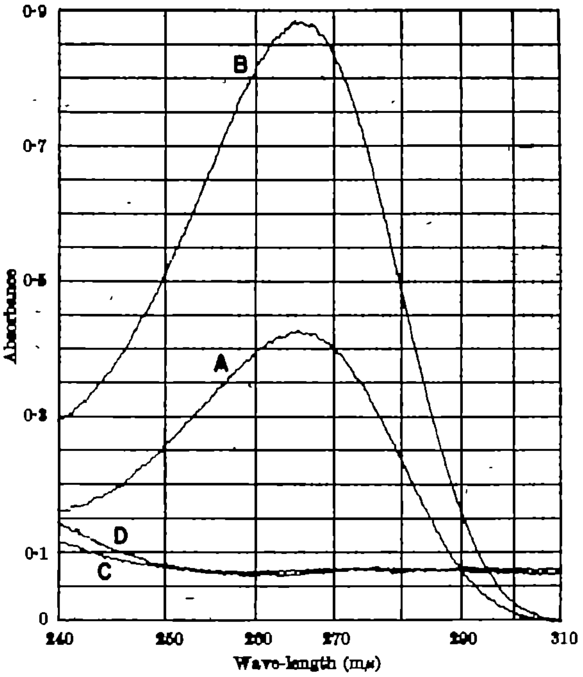

Fig. 1. Absorption spectra of ascorbic acid before and after enzymatic oxidation. The spectrum of 0·1 μmole and 0·2 μmole of ascorbic acid are shown (curves A and B). Curve C is the resulting spectrum of curve B after oxidation by 10 μl. of the enzyme preparation containing ascorbic acid oxidase. Curve D is the spectrum of 10 μl. of the enzyme preparation alone. The reference cell contained 3 ml. of 0·1 M phosphate buffer at pH 5·6 and the sample cell 3 ml. with 0·1 M phosphate buffer containing ascorbic acid and/or enzyme

Details of the enzyme preparation and purification appear elsewhere[4]. In general the tissue was macerated with 5 parts (w/v) 0·1 M phosphate buffer pH 6·5 in a Potter homogenizer. The homogenate was centrifuged at 3,000g for 15 min. The supernatant was retained for enzyme assay or purification. All procedures were carried out at 0–3° C.

The assay was carried out in silica cuvettes with a 1-cm light path at 25° C. Ascorbic acid in 0·5 μmole quantities in 3 ml. of 0·1 M phosphate buffer at pH 5·6 (ref. 4) was added to both the sample cell and the reference cell to compensate for autoxidation and large absorbance values of the ascorbic acid utilized.

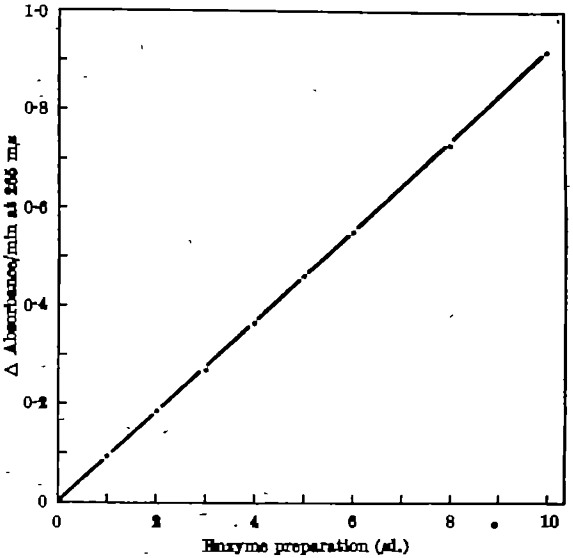

Fig. 2. Proportionality of enzyme activity (change in absorbance) to increased enzyme concentration. The procedure outlined in the text was followed with variation in concentration of the enzyme preparation as indicated. Ascorbic acid concentration was 0·5 μmole in both the reference and sample cell in a total volume of 3 ml. of 0·1 M phosphate buffer at pH 5·6

At zero time, various amounts of the enzyme preparation were added to the reference cuvette, thus allowing for a positive increase in the change in absorbance due to the oxidation of ascorbic acid. This change was recorded continuously at 265 mµ using a time-drive at 1 in./min. The rate was constant and could be extrapolated back to zero time.

The relationship between the amount of enzyme activity (change in absorbance per minute) and enzyme concentration can be seen in Fig. 2.

Absorbance results obtained spectrophotometrically were converted to establish enzyme units obtained manometrically (10 µl. oxygen/min)[1]. Temperature corrections were made on 10 µl. oxygen at 25° C and the corrected volume was converted to µmoles of molecular oxygen. One enzyme unit is equivalent to 0·405 µmole oxygen/min. Ascorbic acid requires only 1 atom of oxygen per molecule oxidized. Therefore, 0·81 µmole of ½ oxygen/min is utilized per enzyme unit. From Daglich's results[2] ascorbic acid has an $E^{1\%}_{1\,\mathrm{cm}}$ of 760 at 265 mµ. From this it was calculated that ascorbic acid has an absorbance of 4·4 per µmole in a 3-ml. volume. Therefore, 1 enzyme unit (0·81 µmole of ½ oxygen/min) would be equivalent to an absorbance change of 3·58/min. Manometric and spectrophotometric assay of enzyme units of the same enzyme preparation gave 11 and 12 enzyme units/ml. respectively.

Presence of Phosphate-mediated Cross-linkages in Hard Tissue Collagens

It has often been suggested that covalent interchain cross-linkages contribute to the stability of collagen fibrils[1,2]. Gustavson[1] speculated that ester bonds exist between free carboxyl groups and the hydroxyl groups of the hydroxy amino-acids. The work of Gallop *et al.*[3] and Hormann *et al.*[4] has substantiated this proposal, implicating carbohydrate or sugar cross-linkage as well. We have found in our work with dentine collagen evidence for still another type of cross-linkage which might apply to the collagens of the calcified tissues, bone and dentine.

Bovine dentine collagen, decalcified with ethylenediamine tetraacetic acid (EDTA) at *p*H 7·5, was found to exhibit markedly different swelling and solubility characteristics in comparison with purified bovine corium collagen. For example, bovine corium collagen swells maximally to 700 per cent at *p*H 2·3 in salt free hydrochloric acid, whereas dentine collagen has no appreciable swelling in the entire acid-range. Bovine corium collagen can be rendered soluble to the extent of 8 per cent by isoionic heating at 60° C for 1 h. With bovine dentine collagen less than 2 per cent is solubilized under the same conditions after 20 h. These results obviously suggest a difference in the mode or extent of the intermolecular stabilization of these two types of collagen.

Comparative chemical analyses showed both collagens to have very similar amino-acid compositions and carbohydrate contents. However, the purified decalcified dentine collagen had a phosphorus content which, expressed in phosphate residues (HPO_4), averaged 0·4 per cent by weight. This phosphorus could not have been the result of residual calcium hydroxyapatite since the calcium/inorganic phosphorus ratio was 0·002 in the purified dentine collagen, compared with a ratio of 2·12 in the undecalcified dentine and 2·16 in pure calcium hydroxyapatite. Since the phosphorus could not be removed by prolonged EDTA extraction or dialysis, it is apparently present in a covalently bound form, presumably as the phosphate. The phosphate content noted here would correspond to 4 phosphate residues per 1,000 amino-acid residues, or to 12 potential cross-linkage sites per tropocollagen monomer unit. Phosphorus is essentially absent in the bovine corium collagens.

The phosphorus-containing moiety is present in a relatively stable form. On conversion of the purified, decalcified dentine collagen into gelatin by heating in water at 110° C overnight it was found that the non-dialysable gelatin still maintained two-thirds its original phosphorus content. Venom and spleen phosphodiesterases, used at their usual optimal *p*H, were ineffective in degrading the purified dentine collagen. The acid swelling and solubility properties of the treated collagen were unchanged after this treatment. However, these results certainly do not rule out the presence of phosphodiester linkages, since the highly organized collagen structure may mask the phosphate groups and diminish the enzyme activity. Likewise, the specificity of these enzymes may not be appropriate; all phosphodiesters are not equally good substrates for every phosphodiesterase[5]. In this regard it is pertinent to note that dentine collagen is also particularly resistant to the action of the usual protein denaturants (for example, 8 M urea) which have a strong denaturing action on bovine corium collagen. Work is in progress on the more accessible phosphate groups in the non-dialysable gelatins obtained by high-temperature hydrolysis. Investigations with oxidizing agents such as sodium periodate suggest that the phosphate may be associated with the carbohydrate moieties in dentine collagen.

These results lead us to suggest that the unusual properties of dentine collagen may be ascribed, in part, to the presence of cross-linkages mediated by phosphate groups. Perlmann[5] has described phosphate esters of three types in other proteins and peptides, —O—P—O—, —N—P—O—, and pyrophosphate, involving serine, threonine and arginine, and possibly carbohydrate. In addition, the hydroxy amino-acids peculiar to collagen, hydroxyproline and hydroxylysine should be considered as potential sites for phosphate ester formation.

Heterogeneity of Urinary Acid Mucopolysaccharides

687 mg of crude urinary acid mucopolysaccharides (preparation *A*) were precipitated from 30 litres of normal human urine according to methods previously described[1].

587 mg of *A* were incubated with crystalline papain at 37° for 70 h in phosphate buffer *p*H 6·30, 0·2 M, containing ethylenediamine tetraacetic acid 0·001 M and cysteine 0·005 M. The digest was applied to a 30 × 1 cm column of 'Dowex 1 × 2' (200–400 mesh, acetate form) and elution was performed with 200 ml. of acetate buffer *p*H 5·90, 0·1 M, followed by 200 ml. of 4 M sodium chloride. The

* The balance is per cent galactosamine.

4-ml. fractions collected were scanned for absorption at 280 mμ and for hexuronic acid content with the carbazole reaction. The protein material was eluted with the acetate buffer; the hexuronic acid-containing material, eluted with 4 M sodium chloride, was concentrated, dialysed, dried (132 mg recovered) and analysed (preparation *B*). The latter was then applied to a 40 × 4 cm column of 'ECTEOLA' modified cellulose (reagent grade; Brown Co., Berlin, New Hampshire), which was washed and eluted stepwise with solutions of increasing chloride concentration, according to the technique described by Anseth and Laurent[2].

Table 1 gives the weight and the analyses of preparations *A* and *B* and of the 10 peaks eluted from the 'ECTEOLA' column.

The 10 peaks were pooled as follows: peaks 1 and 2 = pool 1; peaks 3, 4, 5, 6, 7 = pool 2; peaks 8 and 9 = pool 3; peak 10 = pool 4.

The material from each pool was dissolved in water, electrodialysed and precipitated with 3 volumes of 95 per cent ethyl alcohol containing 0·3 per cent barium acetate. It was then delivered to a 12 × 2 cm column of cellulose, previously equilibrated with 80 per cent ethyl alcohol containing 0·3 per cent barium acetate. Elution was performed with a decreasing alcohol gradient[2] and the peaks were localized by the carbazole and anthrone reactions.

In each chromatographic run, anthrone-positive material was eluted between 80 and 40 per cent alcohol concentration and carbazole-positive material between 40 and 10 per cent alcohol concentration.

The anthrone-positive material from the four pools was combined, electrodialysed, dried and analysed (Table 2). An aliquot was hydrolysed and used for bi-dimensional ascending paper chromatography, using butanol 3, pyridine 2, water 1·5 as first solvent, water-saturated phenol as second solvent and aniline phthalate as the spray for development. The presence of galactose, glucose and arabinose was revealed.

Table 2. MOLAR RATIO OF THE FRACTIONS OBTAINED FROM POOLS 1–4 BY ALCOHOL FRACTIONATION

* Hexosamine is arbitrarily made equal to 1·00.

The carbazole positive material of each pool was eluted in a pattern suggesting the presence of several partially resolved peaks and it was separated accordingly into arbitrary fractions (*A*, *B*, *C*, *D*). Analyses of the different fractions are presented in Table 2.

When the average molar ratio for each pool is compared with the average molar ratio of the 'ECTEOLA' peaks which constituted the pool, a fairly good agreement is observed, with the exception of the nitrogen value for pool 2, which is considerably lower than the average nitrogen value of peaks 3–7 from the 'ECTEOLA' column.

Although a separation of the glucosamine and galactosamine-containing mucopolysaccharides was not achieved with these techniques, nevertheless the results obtained are interesting in two respects.

First, the presence in normal human urine of a mucopolysaccharide containing glucosamine and neutral sugars is suggested. Whether this represents keratosulphate or the prosthetic groups of a glycoprotein cannot be stated at this moment. The small amount of material available (less than 1 mg) did not permit further purification for infra-red analysis or sulphate determination. The fact, however, that the material was retained on the 'ECTEOLA' column and was eluted with increasing salt concentration indicates the presence in it of strongly anionic groups.

Second, analyses of the hexuronic acid-containing fractions clearly indicates a different degree of sulphation. This fact suggests that a mechanism for the desulphation of acid mucopolysaccharides may exist, despite the failure, thus far, to identify the system responsible for it.

Recently, Kaplan and Meyer[3] have injected intravenously, in humans and dogs, highly purified acid mucopolysaccharides at a dose of approximately 1 mg/kg and have followed the ensuing urinary excretion of the polymer injected. Their finding that the small percentage of the material excreted was chemically identical to the injected polysaccharide is in contrast with our data and a possible explanation may be found in the substantial difference between the two experimental conditions. The hexuronic acid-containing fractions isolated in our study have a considerable amount of non-hexosamine nitrogen. This fact in conjunction with the observation of Kaplan and Meyer suggests that desulphation may occur at or near the natural site of occurrence of acid mucopolysaccharides, or at least prior to their entry into the circulation. Even if it is assumed that a highly purified mucopolysaccharide could be accepted as a substrate by the system responsible for desulphation, the question remains as to whether the injected polymers are able: (*a*) to reach the site of the specific desulphating system and (*b*) to compete for it with the already present natural substrates.

Purification of Human Growth Hormone on 'Sephadex G-200'

WE have previously reported the preparation of human growth hormone (HGH) from acetone powders of pituitary glands[1]. The hormone preparations were obtained in high yield and proved satisfactory in clinical investigations but were by no means electrophoretically homogeneous. We wish to describe now a simple and reproducible method for further purification of this material which has resulted in a growth hormone preparation of markedly increased specific biological activity. This preparation, although still not homogeneous, was shown to be substantially purified by the criteria of disk electrophoresis and ultracentrifugation. No serum protein contamination could be detected when this purified preparation was assayed by immunological techniques. A second fraction obtained by this procedure showed some growth hormone activity and in addition possessed considerable luteinizing hormone (LH) potency. This fraction was analysed by immunological techniques and found to contain serum albumin and a smaller amount of serum globulins.

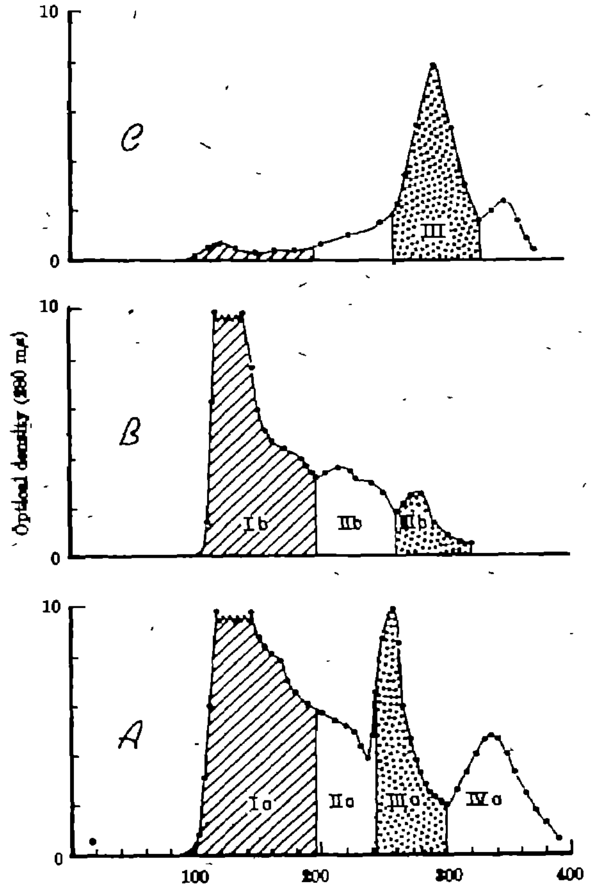

Fig. 1. *A*, Initial chromatography on 'Sephadex G-200'; *B*, chromatography of combined fractions Ia and IIa; *C*, chromatography of combined fractions IIIa and IIIb

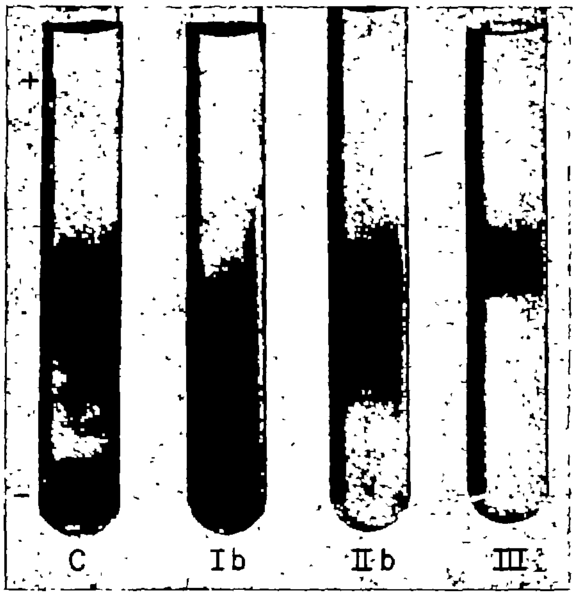

Fig. 2. Disk electrophoresis patterns of starting material (*C*) and fractions I*b*, II*b* and III

In a typical experiment, 1 g of a human growth hormone concentrate (fraction *C*)[1] was dissolved in 17 ml. of ammonium–formate buffer, *p*H 9·2 (0·1 M ammonia, 0·05 M formic acid), and placed on a column of 'Sephadex *G*-200' (1·8 × 120 cm) which had been equilibrated with the same buffer. This buffer was also used for eluting the applied material. The effluent diagram is shown in Fig. 1. Eluate was collected in 7-ml. cuts at 1-h time-intervals. Protein concentrations were estimated by measuring absorption at 280 mμ. The effluent portions were grouped into fractions I*a*, II*a*, III*a* and IV*a* after analysing numerous individual cuts by disk electrophoresis[2,3]. Fraction IV*a* was discarded since it contained mainly salts and nucleic acids. Each of the other combined fractions was lyophilized and then desalted by gel filtration on 'Sephadex *G*-25'. All the material eluted prior to fraction III*a* was combined and again passed over a column of 'Sephadex *G*-200', yielding fractions I*b*, II*b* and III*b*. The effluent diagram resulting from this procedure is also shown in Fig. 1. On the basis of electrophoretic analyses, fractions III*a* and III*b* were combined and again put through a column of 'Sephadex *G*-200' to remove any remaining quantities of fractions I*b* and II*b*. The purified growth hormone thus obtained was designated fraction III as shown in Fig. 1. Fig. 2 shows the patterns which were obtained by disk electrophoresis. Fraction III exhibits considerable improvement in purity when compared with starting material. In addition, fraction III was white in appearance and its solution was essentially colourless, while fractions I*b* and II*b* possessed the same brown, hæm-like colour as the starting material.

The yields and biological activities of various fractions are summarized in Table 1.

All hormone assays were performed by standard procedures previously described[1]. Protein concentration was measured by a modification of the phenol-biuret method as described by Sutherland *et al.*[4].

Ultracentrifugal analyses of fractions II*b* and III at one protein concentration (1·4 per cent) showed sedimentation

Table 1. YIELDS AND BIOLOGICAL ACTIVITIES OF FRACTIONS

constants ($S_{20,w}$) of $4 \cdot 9 \pm 0 \cdot 1$ and $2 \cdot 3 \pm 0 \cdot 1$, respectively. Both fractions sedimented as single boundaries.

It is of interest that fraction II*b* containing luteinizing hormone activity and the human growth hormone fraction (III) were easily separable on 'Sephadex *G*-200', but were not separated by disk electrophoresis. When a 1 : 1 mixture of these two fractions was analysed by disk electrophoresis the main electrophoretic component of fraction II*b* was superimposed on the major component of fraction III. This we found to be true with both 7·5 per cent and 15 per cent acrylamide gels. Whether the prolactin activity of the highly purified fraction III is due to an intrinsic property of human growth hormone or to contamination with prolactin cannot yet be ascertained, since this preparation still contains two significant electrophoretic components.

Effect of Carbon Tetrachloride Intoxication on the Activity of Enzymes of the Urea Cycle in the Liver of the Rat

THERE are many indications that amino-acid metabolism is altered following administration of carbon tetrachloride[1–3]. Smuckler *et al.*[1] have shown that there is an impairment of incorporation of amino-acid into protein as early as 1 h after administration of carbon tetrachloride, probably associated with changes in the structure of the endoplasmic reticulum. The level of activity of ornithine transcarbamylase in the blood also rises rapidly following this type of liver damage[4] while at longer time-intervals there is a decrease in the activity of glutamic dehydrogenase[5] and glutamic-pyruvic transaminase[6].

In investigating the changes following carbon tetrachloride intoxication the measurement of a series of enzymes linked in a metabolic cycle or chain is perhaps of greater interest than that of individual enzymes. The activity of urea cycle enzymes in rats treated with carbon tetrachloride are of significance not only in relation to changes in the metabolism of amino-acids but also because of the different intracellular localization of the enzymes in this cycle. The first two, carbamyl phosphate synthetase and ornithine transcarbamylase, are mitochondrial enzymes and the remainder, arginine synthetase, the rate-limiting step, argininosuccinase and arginase, are in the soluble fraction of the cell[6]. The pattern of change in the activity of these enzymes at different time-intervals after carbon tetrachloride administration was followed in an attempt to correlate the biochemical alteration with the known effects of carbon tetrachloride on cell structure[1,7,8].

The results of these experiments, summarized in Table 1, show that as early as 90 min after treatment of the rats with carbon tetrachloride there was an increase in the two mitochondrial-linked enzymes, carbamyl phosphate synthetase and ornithine transcarbamylase, both as units/g liver and as total activity. At 3 h this effect was even more striking. The other enzymes of the urea cycle, located in the soluble fraction of the cell, remain completely unchanged.

At longer time-intervals (24 h after administration of carbon tetrachloride) the activities of carbamyl phosphate synthetase and ornithine transcarbamylase fell, both in relation to the elevated values at 3 h and, in the case of the former enzyme, in relation to the control value. The specific activity (units/g liver) of the other three enzymes of the urea cycle decreased considerably; there is, however, a large increase in weight of liver at this time following carbon tetrachloride administration, and the total activity of these enzymes in the liver was significantly decreased only in the case of the arginine synthetase system. Flores *et al.*[3] found that the total activity of both arginine synthetase and arginase were decreased.

Recknagel and Litteria[9] have shown that carbon tetrachloride reaches its maximal concentration in the liver at about 2 h after the administration by stomach tube. The present results, showing a significant rise in the activity of carbamyl phosphate synthetase and ornithine transcarbamylase at this time-interval, are among the earliest changes reported in mitochondrial enzymes in carbon tetrachloride intoxication. Rossi and Zatti[10] have reported that the incorporation of phosphorus-32 into liver phospholipids *in vivo* rises at this stage and this may be closely related to some modification of mitochondrial structure. There is, however, no evidence from electron microscopy studies of extensive alterations in mitochondrial morphology as early as 90 min after administration of carbon tetrachloride, and it is generally thought that the first biochemical and morphological alterations are in the endoplasmic reticulum and that the mitochondrial damage takes place later[1,2,7,8].

We thank Dr. R. G. Westall for a supply of argininosuccinate and the Wellcome Foundation for a grant to one of us (F. R.). This work was supported in part by a grant

Table 1 EFFECT OF CARBON TETRACHLORIDE INTOXICATION ON THE ACTIVITY OF ENZYMES OF THE UREA CYCLE IN RAT LIVER

	No. of animals	Units/g liver				
		Carbamyl phosphate synthetase	Ornithine transcarbamylase	Arginine synthetase	Argininosuccinase	Arginase
Control animals	12	250 ± 16	14,190 ± 960	56 ± 4	208 ± 12	98,360 ± 6,340
Time after CCl_4 administration						
90 min	8	348 ± 33	18,880 ± 1,440	67 ± 7	231 ± 10	107,800 ± 13,400
Fisher's *P*		0·016	0 011	N.S.	N.S.	N.S.
180 min	8	383 ± 31	20,480 ± 900	60 ± 5	224 ± 7	92,500 ± 7,370
Fisher's *P*		0·002	< 0·001	N.S.	N.S.	N.S.

Enzyme activities were determined by the method of Brown and Cohen (ref. 11). A unit of enzyme activity is defined as that amount which catalyses the production of 1 μmole of citrulline or urea/h under the assay conditions. The values are expressed as means ± *S.E.M.* Fisher's *P* values for the comparison of the control and experimental groups are given, a difference being considered significant if this is no greater than 0·05. N.S. indicates that the results are not significantly different. The rats were starved overnight and carbon tetrachloride in liquid paraffin (1 : 1 v/v) was given by stomach tube (0·5 ml./100 g body-weight) with the rat under light ether anaesthesia. The control animals were similarly treated with 0·25 ml. liquid paraffin (B.P.)/100 g body-weight.

Visualization of Different Diphospho- and Triphospho-pyridine Nucleotide Dehydrogenase Isozymes on an Agar-gel Plate

We have been looking for a quick and relatively cheap method of screening dehydrogenase isozymes, after electrophoresis. For this purpose, we chose agar gel as a support. We recognize that there is a greater diffusion on agar gel than on starch gel, and also that there is some difficulty in slicing the gel before detecting the isoenzymes. Nevertheless, we prefer agar gel because: (1) it allows a relatively quick electrophoretic partition; (2) it is transparent when dry; (3) it allows the use of the Grabar and Williams technique of immunoelectrophoresis[1].

For this medium, we developed a convenient tetrazolium method which: (1) limits the diffusion during the reaction period: (2) requires a minimal quantity of reaction components, some of them being very expensive; (3) can be used rapidly for different purposes on the same plate.

So far as we know, the method described here seems quicker, cheaper and more versatile than some other isozyme methods using tetrazolium salts[2,3].

The electrophoresis was carried out in a 1 per cent agar gel ('Agar Noble', Difco), in 0·05 M phosphate buffer at *p*H 7 for a good partition of slow components, or in *tris* buffer 0·05 M when phosphate ions are to be avoided. The gel was poured on photographic glass plates (13 × 18 cm for 4 samples, or 18 × 24 cm for 8 samples). Each sample was inserted in a 20 × 3 mm slit cut out of the agar gel with a special punch. The preparation was kept for 105 min in a field of 6 V/cm in the cold (+ 4°). The plate was then brought to laboratory temperature. It was covered with a wooden board which has been wetted before application so that it will stick to the agar gel. This little board outlined 4 or 8, 25 × 150 mm slits which lay over the fractionated samples. In each slit of the board was poured a solution containing the buffer, some substrate, coenzyme, oxidation inhibitor electron transporter (phenazine methosulphate) and tetrazolium salt, in 1 per cent agar gel.

For the detection of lactic dehydrogenase in plasma, 0·1 ml. of plasma was mixed with 0·1 ml. of 2 per cent agar gel. During the time the electrophoresis is being run in phosphate buffer at *p*H 7, the following solutions was prepared:

(*a*) Aliquots of a stock solution of the following compositions, prepared beforehand, and stored at 35° C in 5 ml. vials, were taken from the freezer: sodium lactate, 30 mg; diphosphopyridine nucleotide (Sigma), 2 mg; sodium azide, 10 mg; 3(4,5 dimethyl thiazolyl 1,2)2,5 diphenyl tetrazolium bromide (ATT: Mann), 2 mg (dissolved in 0·2 ml. acetone); *tris* buffer (0·05 M, *p*H 8·2), 2 ml.

The solution was transferred to a hæmolysis tube and warmed to 42° C. To this was added 2 ml. of 2 per cent agar gel in water, then 0·2–0·5 mg of sodium phenazine methosulphate (Sigma). After quick mixture, it was poured in one of the slits and immediately covered, to protect the complex from light.

After incubation for 1 h at 37° C in a damp atmosphere or 2 h at laboratory temperature, the isozyme pattern was very apparent. If desired it could be covered with a thin layer of 1 per cent agar gel in order to obtain a flat surface. Afterwards, the plate was fixed for 2 h in 2 per cent acetic acid. The preparation was then covered with filter paper and dried at 37° C.

The plate with the dried film could be kept indefinitely in the dark, and filed as a laboratory record.

We applied this system to visualize the isozymes of lactic acid dehydrogenase of normal and pathological plasma, as well as the isozymes of lactic, malic, isocitric, glutamic, β-hydroxybutyric and glucose-6-phosphoric acid dehydrogenases in rat liver homogenates. In addition, we applied our system after plasma immunoelectrophoresis. We are now examining the coloured precipitation lines obtained to determine whether they are enzymatically active.

PHYSIOLOGY

Uterine Relaxant Properties of Bradykinin *in vitro*

At the present time, there is no effective means of blocking uterine contractions in order to prevent premature labour. A drug which would block uterine contractions may reduce the incidence of prematurity. Of all infant deaths occurring at the New York Hospital in 1961, 72·5 per cent were prematurely born.

Bradykinin was synthesized by Boissonnas, Guttmann and Jaquenoud[1] and was shown to be a nonapeptide. Elliot, Horton and Lewis[2] demonstrated the great sensitivity of the isolated rat uterus to bradykinin as indicated by increased contractility. Because of this constrictor response in the rat, Berde and Saameli[3] investigated the effect of bradykinin on the human uterus *in situ*. Intravenous injections of 2 μg/kg were without any effect on the human uterus. These authors concluded that bradykinin had no constrictor activity on the human uterus. Because of its known relaxant effect on smooth muscle, bradykinin in various concentrations was applied to human uterine muscle. Strips were placed in an organ bath of 5 c.c. capacity containing oxygenated mammalian Krebs's solution[4] which was kept at constant temperature and *p*H.

Bradykinin was applied 112 times to 32 non-pregnant uteri and 52 times to 13 pregnant uteri at the time of section. The effect on tonus, frequency and amplitude maximum was recorded after a pattern of spontaneous or induced contractions was established. A reduction in at

Table 1. Effect of Bradykinin on the Human Uterus *in vitro*

	Concentration of bradykinin (μg/ml.)						
	0·2	0·4	0·6	0·8	1·0	1·2	1·4
Non-pregnant: Incidence of response	11/20 55%	27/32 84·5%	17/18 94·5%	29/30 96·5%	12/12 100%		
Pregnant: Incidence of response	6/10 60%	12/12 100%	3/4 75%	13/13 100%	6/6 100%	4/5 80%	2/2 100%

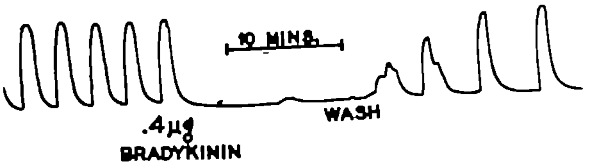

Fig. 1. In the non-pregnant uterus prompt relaxation following bradykinin with recovery is demonstrated

least one of these variables was considered a relaxant response. In the non-pregnant uterus a concentration of 0·2 μg/ml. produced a significant relaxant response in 57 per cent of the tests. At levels of 0·8 μg/ml. a maximum response in the non-pregnant uterus resulted in a complete inhibition of all contractions. In the pregnant uterus, as indicated in Table 1, slightly higher concentrations were required to inhibit contractility. Oxytocin-induced contractions required slightly higher levels of bradykinin than the spontaneous variety. This was particularly true in the pregnant muscle. Fig. 1 shows a low concentration of bradykinin-inhibiting contractions of the non-pregnant uterus in the presence of oxytocin and a return to the original pattern following a wash.

The high potency of this compound on human uterine muscle with its inhibiting action on contractions is of considerable interest. A study of bradykinin on *in situ* human uterus is indicated to determine its possible effect in preventing the onset of premature labour. The known hypotensive effect of bradykinin makes it unlikely that its use alone may be practical. A combination of a hypertensive agent, such as angiotensin, with bradykinin may provide effective therapeutic agent.

Effect of Hydrogen Ion on the Rates of Migration of Sodium and Potassium Ions: Possible Relationship to Magnetism

I have read with interest the recent communication of Salminen[1] on the effect of hydrogen ions on the differential rates of migration of sodium and potassium ions. I believe this may relate to an experiment which I have performed demonstrating a differential effect of external magnetic fields on the concentration of these ions across a semipermeable membrane.

A 4-in. length of 'Cellophane' tube of the sort used in the artificial kidney apparatus was filled with the usual dialysate solution for blood lavage, the ends were sealed and it was suspended in a beaker of the same solution. The pole of a permanent magnet capable of lifting a 125-lb. weight of steel was placed against the 'Cellophane' tube so that the strongest magnetic field was inside the tube. After incubation for 9 h the concentration of ions in the two compartments was determined by standard methods available in the clinical laboratory. The experiment was repeated five times, and in each instance the results were similar to those given in Table 1.

Table 1

	Mg	Ca	K	Na	Cl	HCO₃
'Cellophane' tube	3·5	4·5	4·9	160	122	*
Beaker	3·5	4·5	4·4	151	123	*

All values in m.equiv./l.
* Present but not determined.

The sodium, potassium and chloride ions were always more concentrated in the 'Cellophane' tube than in the surrounding bath. This difference could be increased greatly by decreasing the volume of solution inside the 'Cellophane' tube. The increase of potassium was always proportionately greater than the sodium. The failure to demonstrate any effect on magnesium and calcium may have been due to formation of unionized complexes with bicarbonate.

I have surmised that the movement of electrons along the chains of respiratory enzymes in the mitochondria and the concurrent movement of hydrogen ions in the same direction generate electromagnetic fields, as do other electric currents, and that these magnetic forces may be a determining factor in the characteristic proportions of intracellular ions, and thereby related to the mechanism of the 'salt pump'.

---

[1] Salminen, S., *Nature*, **195**, 908 (1962).

Dr. George's communication contains no mention of control experiments without a magnetic field. Thus it is open to question whether the results, interesting as such, are related to some factors other than the magnet. The fact that the experiments were performed with dialysate fluid made for blood lavage suggests that its P_{CO_2} would have been higher than that of the air. The loss of carbon dioxide from the beaker might have produced a higher gradient of H⁺ in the 'Cellophane' tube, resulting in an accumulation of other cations in this phase, as was found, for example, by Teorell in his classical work[1]. That the effect of H⁺ on the rates of simultaneous non-equilibrium migration of Na⁺ and K⁺ is different was experimentally found in my communication referred to by Dr. George.

A theoretical treatment of these problems is in progress by our group, using the concepts of irreversible thermodynamics.

Effect of 3:5:3′-triiodothyroacetic Acid on the *In vitro* Oxygen Uptake of Leucocytes of Hypopituitary Patients

Neither L-3 : 5 : 3′-triiodothyronine (T_3) nor 3 : 5 : 3′-triiodothyroacetic acid (TRIAC) affect the uptake of oxygen by leucocytes from normal individuals studied *in vitro* with the direct method of Warburg with a modified Krebs's No. 2 buffer. When, however, these *in vitro* investigations are carried out with leucocytes from patients with primary hypothyroidism, an immediate stimulation of oxygen uptake can be demonstrated with TRIAC although no effect is produced by T_3 (ref. 1).

The opportunity was taken to carry out similar investigations on the leucocytes from 5 other patients who were also hypothyroid. In these patients, however, the hypothyroid state was the result of hypopituitarism and there was clinical and investigational evidence of the other expected endocrine deficiencies.

Blood was collected in heparinized siliconed tubes according to the method of Bisset and Alexander[4]. The leucocytes were isolated after sedimentation with dextran (6 per cent w/v in 0·9 per cent sodium chloride solution). From 80–100 ml. of blood from each patient sufficient leucocytes were obtained to set up 4 flasks, each of which contained approximately 40–50 million leucocytes in Krebs's No. 2 buffer. TRIAC in two concentrations, 25 and

50 µg/100 ml. medium, was added to duplicate flasks. The oxygen uptake of the leucocytes was examined by the direct method of Warburg using air as the gas phase. Readings were taken every 15 min. The results were expressed as the uptake of oxygen in µmoles/h/10^7 leucocytes.

Table 1. UPTAKE OF OXYGEN BY LEUCOCYTES (µMOLES/H/10^7 LEUCOCYTES)

	Control	µgm TRIAC/100 ml. medium 25	µgm TRIAC/100 ml. medium 50
1.	0·088	0·090	0·089
2.	0·100	0·103	0·100
3.	0·112	0·107	0·112
4.	0·084	0·077	0·079
5.	0·078	0 078	0·098

The results are shown in Table 1. Each value is the average of 2 readings. Patients 1–4 were receiving no therapy. Although they were hypothyroid, the uptake of oxygen by their leucocytes failed to show the stimulation produced by TRIAC which is usually found in patients with primary hypothyroidism. Patient 5, however, although he was also hypothyroid, was receiving maintenance treatment with cortisone. Unlike the other patients, there was a significant increase in the uptake of oxygen by his leucocytes as a result of incubation with TRIAC. It is possible that, in this patient, cortisone facilitated the access of the thyroid hormone to the site of action. The absence of the expected stimulation of oxygen uptake by TRIAC in patients with untreated secondary hypothyroidism may therefore, in part at least, be related to the secondary adrenal deficiency. Our findings at present do not permit further speculation, but once more emphasize the importance of the inter-dependence of the endocrine glands.

Stimulation of Secretion of Insulin by Adenosine-triphosphate

IN previous papers[1–4] we showed that different metabolites, both *in vivo* and *in vitro*, produce insulin secretion which we measured by the method of the epididymal fat of the rat. In view of some of these results we decided to ascertain whether the intravenous injection of ATP was a stimulant to insulin secretion; although we are aware that the point of view actually held is that the metabolic processes affected by this nucleotide are intracellular.

Animals from our rat colony (140–160 g) were intravenously injected with ATP 1·7 × 10^{-3} M (total volume 0·25 ml., *p*H 7) and killed immediately after the injection (10–20 sec.). The evaluation of the plasma insulin effect and glucose uptake of the diaphragm and epididymal fat were carried out following the method already described[3]. As control of the effect of the ATP injection, we injected the same quantity of hydrolysed ATP (1·0 hydrochloric acid for 10 min at 100° C) and other experiments were also realized with hydrolysed ATP versus control.

As is shown in Table 1, the injection of ATP produces secretion of insulin, which shows itself by a greater plasma insulin effect and the increase of the glucose uptake of the diaphragm and of the epididymal fat. This action is similar to, although much speedier than, that obtained when we used glucose and *l*-leucine injections. On the other part, the hydrolysed ATP has no effect. The results obtained show the need to know the mechanism of action implied by possible extra-cellular activity of this nucleotide.

We thank Dr. S. Ochoa for his advice. This work was supported in part by a grant from J. March Foundation.

Transport of Potassium Ions in the Rat's Intestine

THE transport of sodium ions across the epithelium of the small intestine of the rat seems to be an active process (for a review of the evidence see Durbin, Curran and Solomon[1]). This active transport of sodium ions may be responsible for the potential difference existing across the gut wall, the mucosal side of which is negative with respect to the serosal side. In the jejunum the amplitude of this potential reported in the literature ranges from about 8 mV (refs. 2, 3) to 12 mV (ref. 4); the potentials in the ileum are smaller[3].

Evidence for the active transport of ions other than sodium across the epithelial membrane is slight and the possibility has frequently been discussed that many cations and anions move passively along their electrochemical gradients[1,2,5,6]. We have been interested in the transport of potassium ions by the epithelial cells of the rat's jejunum and ileum. From measurements of the concentration of this ion on both sides of the cellular barrier between mucosa and serosa, together with determinations of the transcellular potential, we have come to the conclusion that the total electrochemical potential of the potassium ions is the same on both sides of the epithelial membrane. This provides experimental evidence for the suggestion that the transport of potassium ions is a passive process and there is no need to postulate an active transport mechanism.

The rat's small intestine was divided into 'jejunal' and 'ileal' portions and the lumen was perfused *in vitro* by the method described by Gilman and Koelle[7]. The perfusion fluid was Krebs's bicarbonate solution gassed with 95 per cent oxygen and 5 per cent carbon dioxide, at *p*H 7·4 and at 37° C. It flowed at a rate of 5–7 ml./min; this provided adequate oxygenation and presented to the mucosal surface a fluid of constant composition. The relationship between the potassium concentrations of the fluid presented to the mucosal surface and that transported by the epithelium to the serosal side was obtained in experiments in which the gut segments were maintained in a chamber where the serosal surface was exposed to 95 per cent oxygen, 5 per cent carbon dioxide and water vapour. Transported fluid, escaping from the serosal surface, cut blood vessels and lymphatics, was collected so that a direct analysis of the composition of the fluid actually transported could be made. Table 1 shows that for both the jejunum and ileum the potassium concentration in the fluid transported to the serosal side was less than that in the perfusing mucosal fluid (as already observed by Smyth and Taylor[8]), both when the latter concentration was 6 mM and when it was 12 mM.

Table 1

	Chemical experiments			Electrical experiments
	Mucosal potassium concentration (mM)	Mucosal potassium concentration / Serosal potassium concentration*	Potassium equilibrium potential† (mV)	Measured potential mucosa–serosa† (mV)
Jejunum	6	1·56 ± 0·03 (25)	11·8 ± 0·5	11·6 ± 0·8 (9)
	12	1·54 ± 0·03 (7)	11·6 ± 0·3	11·2 ± 0·5 (6)
Ileum	6	1·46 ± 0·05 (23)	9·7 ± 0·9	9·3 ± 0·7 (6)
	12	1·52 ± 0·02 (7)	10·9 ± 0·8	10·2 ± 0·6 (6)

Figures are means and are *S.E.*'s; Nos. of experiments are given in parentheses.

* Determined in sample collected over period of 1 h.

† Mucosal side negative.

Potential measurements were made with calomel electrodes with saturated potassium chloride bridges (Beckman fibre junction reference electrodes) feeding into a low grid current cathode-follower. In the experiments in which potentials were measured the gut segments were immersed in 25 ml. of fluid of the same composition as that used to perfuse the lumen of the gut. The serosal electrode dipped into this pool and thus made contact with the whole of the serosal surface of the segment being studied; the mucosal electrode dipped into the fluid perfusing the lumen. The electrical potential measurements were thus made in separate experiments and under somewhat different experimental conditions from those where the chemical composition was determined. This measured potential was assumed to be a reliable measure of the potential which existed across the gut wall in the chemical experiments for the following reason. There is ample evidence that the gut transports well in the presence or absence of bathing fluid on the serosal side[7-9]; thus in the electrical experiments although the composition of the bulk of the fluid on the serosal side was Krebs's solution (or a Krebs's solution modified by transported fluid) the fluid immediately outside the serosal pole of the epithelial cell (that is, the fluid important with respect to the potential difference across the epithelium) would have had the composition of the transported fluid, as in the chemical experiment. The advantage of using the two procedures was that the potential and the chemical determinations were each made under conditions which permitted the greatest accuracy of measurement.

In six experiments on the jejunum the potential initially recorded (within 10 min of mounting the gut in the perfusing apparatus) was 11·8 ± 0·9 mV; during the next 20 min the potential rose to a maximum of 12·7 ± 1·0 mV and thereafter declined to a value of 9·8 ± 1·2 mV at the end of 1 h. In the ileum the corresponding potentials were 9·2 ± 1·2, 10·3 ± 0·7 and 8·2 ± 0·9 mV. This falling off of the potential did not seem to be due to any change in the composition of the serosal fluid; when this fluid was replaced by fresh Krebs's solution there was little or no change in the potential. In each experiment six potential measurements were made at intervals of about 10 min during the first hour and the value of their arithmetical average determined. The mean of these average values in all the experiments is given in Table 1, for experiments in which the potassium concentration in the Krebs's solution perfusing the lumen was normal (6 mM) and for experiments in which it was twice this value.

Correlation between chemical and potential measurements. If potassium is free to diffuse across the gut wall then at equilibrium for this ion the concentration difference observed must be associated with a potassium equilibrium potential (E) the magnitude of which is given by the relationship, $E = \frac{RT}{F} \log [K]_m/[K]_s$, where R is the gas constant, T the absolute temperature, F Faraday's constant and $[K]_m$ and $[K]_s$ are the mucosal and serosal concentrations of potassium respectively. The average ratio of $[K]_m/[K]_s$ in 25 experiments on the jejunum (using 6 mM potassium Krebs's solution) was 1·56 ± 0·03; the mean value of the potassium equilibrium potential obtained by averaging the individual potentials calculated from each experimentally determined ratio was 11·8 ± 0·5 mV. The corresponding values for 23 experiments on the ileum were 1·46 ± 0·05 for $[K]_m/[K]_s$ and 9·7 ± 0·9 mV for the mean potassium equilibrium potential. As can be seen from Table 1 the predicted potentials are very nearly the same as the potential differences actually measured (11·6 ± 0·7 mV for the jejunum and 9·3 ± 0·8 mV for the ileum) when averaged over an hour to correspond with the chemical measurements which were made on samples collected during an hour. This close agreement between the predicted and measured potential difference was also obtained in the experiments using 12 mM potassium Krebs's solution.

The net difference in electrochemical potential for the potassium ion on the two sides of the gut wall, $\frac{RT}{F} \log [K]_m/[K]_s - E$, is thus practically zero. Whereas this finding does not exclude the possibility that potassium is actively transported, the simplest explanation of our results is that potassium ions move passively across the wall of the jejunum and ileum and that their distribution is determined by a pre-existing potential across the gut which is at present believed to result, according to the work cited here, from the active transport of sodium ions.

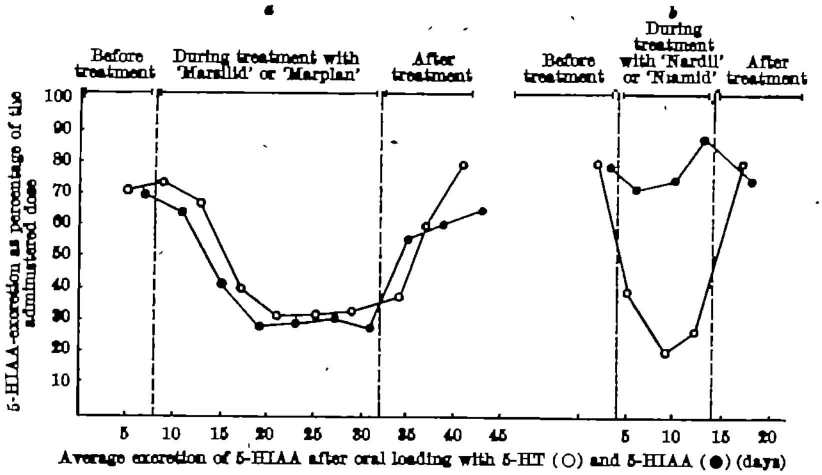
PHARMACOLOGY

Variable Action of Monoamine Oxidase-inhibiting Hydrazines on Serotonin Metabolism

Recently, van Praag and Leijnse[1] reported an interesting finding concerning monoamine oxidase-inhibiting hydrazines 'Marsilid' (iproniacid) and 'Marplan' (isocarboxazid) on serotonin metabolism. They found that



Measured in six subjects, before, during and after treatment with 'Marsilid' or 'Marplan' (from van Praag and Leijnse)

Measured in four subjects, before, during and after treatment with 'Nardil' or 'Niamid'

Fig. 1

during treatment with these drugs the increase in the excretion of 5-hydroxyindolylacetic acid (5-HIAA) in urine after oral feeding of 5-HIAA decreased in the same way as after oral administration of serotonin (5-hydroxytryptamine = 5-HT) (Fig. 1*a*). They concluded from this result that:

(1) Monoamine oxidase-inhibiting hydrazines have a similar and practically synchronous effect on 5-HIAA excretion after loading with serotonin and 5-HIAA.

(2) This effect is brought about through the same mechanism of action.

(3) The action of the so-called monoamine oxidase-inhibiting hydrazines on the serotonin loading test cannot be a result of the inhibition of monoamine oxidase.

In re-examining the work of van Praag and Leijnse, I have obtained the same results for 'Marplan'. I have not investigated 'Marsilid' due to the danger of toxic side effects. However, I feel that the conclusions drawn by van Praag and Leijnse are erroneous. I have found that treatment with two other monoamine oxidase-inhibiting hydrazines, 'Niamid' (isonicotinyl-benzylcarbamylethylhydrazine) and 'Nardil' (phenylethylhydrazine), decreases 5-HIAA excretion only after loading with serotonin while, however, the 5-HIAA excretion after loading with 5-HIAA itself is not influenced (Fig. 1*b*).

The conclusions are:

(1) Only 'Marsilid' and 'Marplan' among the four monoamine oxidase-inhibiting hydrazines influence 5-HIAA excretion after loading with serotonin or 5-HIAA in the same way. 'Niamid' and 'Nardil' reduce the 5-HIAA excretion only after loading with serotonin.

(2) I believe that it is, therefore, improbable that the effect of 'Marsilid' and 'Marplan' on 5-HIAA excretion after loading with serotonin and 5-HIAA is exerted through the same mechanism.

(3) The action of monoamine oxidase-inhibiting hydrazines on the serotonin loading test is certainly an expression of monoamine oxidase-inhibition, for those monoamine oxidase-inhibitors not belonging to the hydrazine series, such as benzyl-methyl-propinylamine, prevent the formation of 5-HIAA from serotonin in the same way. An action of these monoamine oxidase-inhibitors on 5-HIAA excretion after loading with 5-HIAA was not observed[2].

I should like to interpret the action of 'Marsilid' and 'Marplan' on 5-HIAA excretion after loading with 5-HIAA as a side effect of these two substances. The results of Stock and Westermann[3] also point in this direction. They found that inhibitors of monoamine oxidase exert a pharmacological action that is often independent of their capacity to block the enzyme. These authors are of the opinion that the side effects of monoamine oxidase-inhibitors can be of just as much importance in their ability to bring about other pharmacological, biochemical and, possibly, also therapeutic actions as their ability to inhibit monoamine oxidase.

Further investigation will be needed to clarify if the decrease in the 5-HIAA excretion after loading with 5-HIAA is an effect of 'Marsilid' and 'Marplan' without therapeutic meaning, or if there is a relationship to clinically important symptoms such as toxic side effects. With the introduction of new monoamine oxidase-inhibitors in the future, the behaviour of 5-HIAA excretion after loading with 5-HIAA must be examined.

The decrease in 5-HIAA excretion after oral loading with 5-HIAA brought about by 'Marsilid' and 'Marplan' is of general interest, since it is possible that 5-HIAA is not the end product of serotonin catabolism, but is further transformed in the body under certain conditions. Preliminary results indicate a change in the indole ring. Paper chromatographic investigation of urine after loading with 5-HIAA shows a strong colour reaction with Ehrlich's and diazo reagent corresponding in position on the chromatogram to 5-HIAA. With treatment with 'Marplan' after loading with 5-HIAA, it is no longer possible to detect diazo or Ehrlich-reactive material in the chromatogram[2,4].

Methods. 5-HIAA excretion in urine was determined by the method of Udenfriend *et al.*[5,6]. Urine was quantitatively collected for 8 h after loading with serotonin or 5-HIAA. Those factors interfering in the determination were eliminated[6,7]. Serotonin was administered as serotonin creatinine sulphate. Both serotonin and 5-HIAA were dissolved in a few millilitres of hot water. The doses were 0·15 mg/kg body-weight 1,5-hydroxytryptophan and equimolar amounts of serotonin and 5-HIAA.

Two tablets of 'Niamid' or 'Nardil' were administered mornings and evenings.

This work was supported by the Deutsche Forschungsgemeinschaft. We should like to thank the following firms for the supply of chemicals: Abbott, Chicago (benzyl-methyl-propinylamine); Gödecke, Memmingen ('Nardil'); Pfizer, Karlsruhe ('Niamid'); Sandoz, Basel (serotonin creatinine sulphate and 5-HIAA).

Diminution of Imipramine Mortality in Hypothyroid Mice

A PREVIOUS report described enhancement of imipramine toxicity in hyperthyroid mice[1]. This work had been prompted by the observation of a clinical case in which the simultaneous exhibition of imipramine and thyroid hormone had preceded a bout of paroxysmal auricular tachycardia[2]. Although we had no similar clinical experience to commend our present work, we nevertheless considered it of interest to test the effect of hypothyroidism on imipramine mortality.

100 adolescent male Swiss–Webster mice were obtained. 50 were given a standard laboratory diet and 50 were

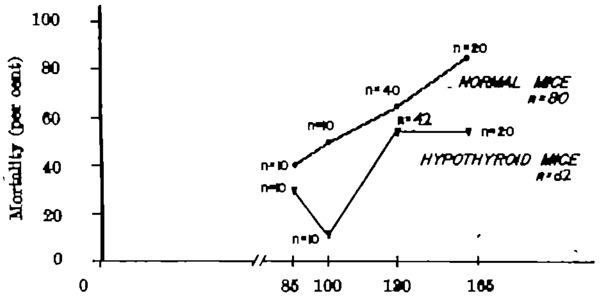

Fig. 1. Intraperitoneal imipramine acute (2 h) mortality in adult, male, Swiss–Webster white mice

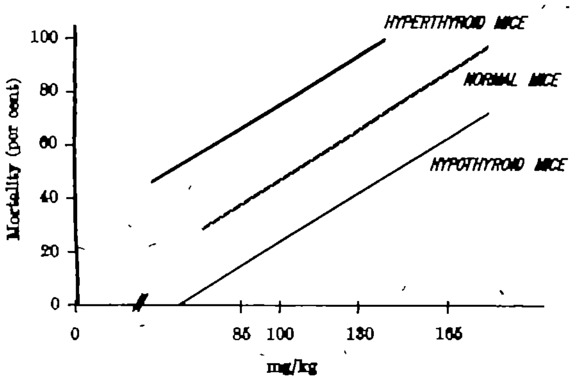

Fig. 2. Idealized imipramine dose–mortality curves in adult, male, Swiss–Webster white mice according to thyroid status

treated in the same way except that 0·2 per cent propyl thiouracil (PTU) was added to their drinking water. All mice were weighed at intervals of 48 h. Throughout this preparatory period the PTU-fed mice showed retarded gain in weight. On the sixteenth day these mice were found to use slightly less oxygen per unit time than the normal mice. At this time, using spontaneous behaviour as a criterion, five judges were able to identify cages containing PTU-fed mice versus 'normal cages' 15 times out of 25 tries (not significant).

The same day the mice were injected intraperitoneally with a solution of lyophilized imipramine in saline (10 mg/ml.). At the dose of 100 mg/kg, 5 of 10 normal mice died; 1 of 10 PTU-fed mice died. At the dose of 130 mg/kg, 12 of 20 normal mice died; 12 of 20 PTU-fed mice died. At the dose of 165 mg/kg, 17 of 20 normal mice died; 11 of 20 PTU-fed mice died. On the basis of these preliminary data we suspected that hypothyroidism reduced imipramine mortality. We attributed our failure clearly to demonstrate the phenomenon to the probability that the PTU-fed mice had been only mildly hypothyroid.

Another group of mice were chosen for further study. 30 were given a standard diet and 32 were given 0·2 per cent PTU water for 30 days. At the end of this time the PTU-fed mice were incontrovertibly hypothyroid. They had gained less weight than normals, their coats were dull and yellowish, and they appeared sluggish. At the dose of 85 mg/kg, 4 of 10 normal mice died; 3 of 10 PTU-fed mice died. At the dose of 130 mg/kg (the non-discriminating dose in the first experiment), 13 of 20 normal mice died; 12 of PTU-fed mice died. All deaths occurred within 2 h of injection. The mice that died, in both classes, showed pre-terminal hyperactivity, convulsions and occasional opisthotonous, as had hyperthyroid mice[1].

Results from the two experiments are combined in Fig. 1. The χ^2 value for an over-all analysis of difference is 4·30 ($P = < 0·05$).

Fig. 2 presents in idealized form the results of work recorded here plus the results from ref. 1. In mice, intraperitoneal imipramine presents a sloping dose–mortality curve. The curves for hyper-, hypo- and eu-thyroid mice are parallel over the dose-range tested. Hyperthyroid mice are significantly more sensitive, and hypothyroid mice significantly less sensitive, than euthyroid mice, to the mortal effects of imipramine.

HÆMATOLOGY

Synthesis of Hæm in Normal and Leukæmic Leucocytes

RECENT investigations suggest that the formation of hæm from iron and protoporphyrin is enzymatic in avian erythrocytes[1–4], rat liver[5,6] and canine muscle[7]. The hæmoproteins, such as catalase, peroxidase and the cytochromes, exist in leucocytes[8]; however, the origin of hæm for these proteins is not apparent. The present study concerns the formation of hæm in a leucocyte system.

Leucocytes were isolated from human blood which was collected in siliconized glassware containing heparin. The blood was mixed with an equal volume of 4·5 per cent dextran, and allowed to sediment until the plasma rich leucocyte layer and the erythrocyte mass were clearly separated. The leucocyte layer was removed and centrifuged at 320*g* for 5 min. The sedimented leucocytes were resuspended in 1·5 vol. of de-ionized, distilled water and homogenized in a motor-driven glass homogenizer for 5 min at 4°. 5-ml. aliquots of homogenate, obtained from $2·1 \times 10^8$ to $1·5 \times 10^9$ leucocytes, were added to reaction mixtures which contained 0·13 μc. ferrous citrate (iron-59), 0·5 μmole protoporphyrin, 10 μmoles cysteine and 1,000 μmoles *tris* buffer *p*H 7·8, in a final 10-ml. vol. with 0·15 M sodium chloride. This mixture was incubated for 4 h at 37° and the reaction stopped with 0·1 M potassium cyanide. Carrier hæm was added, the total hæm was isolated, and the radioactivity of the recrystallized hæm was determined. Hæm synthesis was measured as the per cent incorporation of added radioiron into hæm (per cent uptake iron-59). Synthesis was considered to be significant if the total counts per minute of the isolated hæm were greater than twice background and the per cent uptake of iron-59 was greater than 2 per cent. In each experiment, 5 ml. of saline and 5 ml. of a hæmolysate, prepared from the patient's sedimented erythrocytes, were substituted as controls for the leucocyte homogenate. Incorporation of radioiron under these conditions was always less than 1 per cent. 5 ml. of an active avian hæmolysate was also included as a control in each experiment and the uptake of iron-59 was always greater than 5 per cent.

The results are shown in Table 1. When leucocytes isolated from normal individuals were used little, if any, hæm synthesis occurred and the uptake of iron-59 was less than 1·0 per cent. Similarly, when leucocytes from two patients with chronic myelocytic leukæmia, two patients with chronic lymphocytic leukæmia, and one patient with monocytic leukæmia were used, the uptake of iron-59 was less than 2·1 per cent. However, if the source of leuco-

Table 1. Hæm Synthesis in Leucocytes

Exp. No.	Patient	Diagnosis	Total No. of blasts	Percentage uptake ^{59}Fe
1	G. K.	Normal	0	0·4

10	N. L.	Myeloblastic	$1·1 \times 10^9$	29·9
11	A. G.	Myeloblastic	$3·3 \times 10^9$	11·5
12	C. C.	Myeloblastic	$3·1 \times 10^9$	4·9
13	L. W.	Lymphoblastic	$1·3 \times 10^9$	26·9
14	B. C.	Lymphoblastic	$3·7 \times 10^9$	6·9

cytes was from patients with either acute myeloblastic or acute lymphoblastic leukæmia, considerable synthesis of hæm occurred. When leucocytes from 3 patients with acute myeloblastic leukæmia were used the uptakes of iron-59 were 29·9, 11·5 and 4·9 per cent. In two experiments with leucocytes from patients with acute lymphoblastic leukæmia, the uptakes of iron-59 were 26·9 and 6·9 per cent.

Since the enzymatic synthesis of hæm is similar in avian erythrocytes[1–4], rat liver[5,6], and canine muscle[7], a preliminary characterization of this reaction was performed with leucocytes from patient L. W. Preheating the leucocyte homogenate to 80° for 10 min resulted in complete loss of activity. Optimal activity occurred at approximately pH 7·8. When the concentration of the homogenate was increased, there was a proportional increase in per cent uptake of iron-59. The rate of the reaction was linear for the first 30 min and approached a maximum after incubation for 4 h. As regards these characteristics, the synthesis of hæm in leucocytes appears to be similar to that described for other tissues[1–7].

In summary, hæm synthesis can be demonstrated in leucocytes obtained from patients with acute leukæmia, but not in leucocytes obtained from normal individuals or patients with chronic leukæmia. This difference probably results from the high concentration of lymphoblasts or myeloblasts in the blood of patients with acute leukæmia.

These findings are interesting in view of Vannotti's observation that leucocytes isolated from patients with acute leukæmia could convert δ-aminolævulic acid to porphobilinogen and then to porphyrin[9]. However, when leucocytes were isolated from normal individuals, patients with infections, or pregnant women, δ-aminolævulic acid was converted to porphobilinogen, but porphyrin formation was not observed.

Hypohaptoglobinæmia in an American Negro Family

With the demonstration that random population pairs and dizygotic twins show greater intra-pair variability than monozygotic twins in serum haptoglobin (Hp) level, evidence for the genetic regulation of this protein has been presented[1]. This work also demonstrated that the normal values for haptoglobin phenotypes Hp 2–2 and Hp 2–1 are lower than those for Hp 1–1. If these differences are genetically determined, a similar mechanism involving the *Hp* 2 allele may be operative in a benign, genetically determined deficiency of serum haptoglobin[2–4]. A family of Dominican descent in which nine members drawn from two generations had haptoglobin-levels ranging from 6 to 52 mg/100 ml. and Hp 2–1 and Hp 2–2 phenotypes has also been reported[5]. On the basis of the available pedigrees, inheritance of this trait via a recessive haptoglobin allele (Hp^{0}) or a simple non-allelic dominant has been excluded. Although so far all Caucasians with hypohaptoglobinæmia have been, when typable, phenotypically Hp 2–1 or Hp 2–2, a strong association between the Hp 2^{m}–1 phenotype and haptoglobin depression exists in the American Negro[6]. We have studied an American Negro family, containing a pair of monozygotic twins in which hypohaptoglobinæmia unrelated to hæmolysis existed throughout an entire generation of offspring.

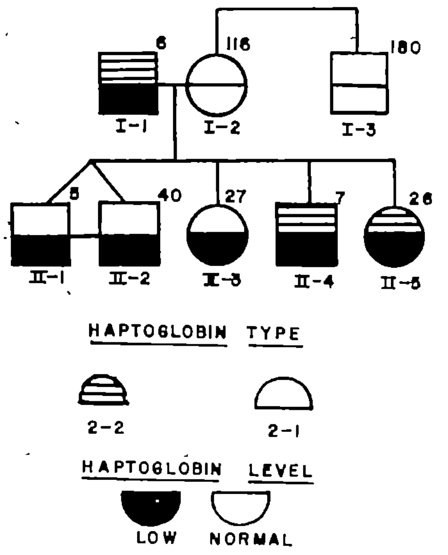

Fig. 1

The methods used in this investigation to exclude hæmolysis and hæmoglobin abnormalities and to confirm legitimacy have been described elsewhere[6]. A complete blood count was normal in all family members except II–1, who was in the nephrotic phase of glomerulonephritis when studied. Serum haptoglobin was measured on serial specimens by the peroxidase–guaiacol method of Connell and Smithies and haptoglobin phenotyping performed after vertical starch gel electrophoresis in borate buffer at pH 8·6 (refs. 7, 8). The family pedigree and haptoglobin phenotypes are presented in Fig. 1. Haptoglobin values are given as a suprascript for each family member. Age ranged from 17 to 52 years. The values considered subnormal are distinctly abnormal in our laboratory for Hp 2–1 and Hp 2–2, and are below the mean normal values obtained by Bayani-Sioson *et al.* using the peroxidase–guaiacol determination. Haptoglobin depression was found in 6 family members all having Hp 2–1 or Hp 2–2 phenotypes. Values ranged from 6 to 45 mg/100 ml. in these individuals. Despite his nephrotic syndrome, the characteristic rise in α-2-globulin was not observed in II–1 and haptoglobin depression was found in his otherwise normal identical twin. Although marked proteinuria may be associated with considerable haptoglobinuria, only trace quantities of haptoglobin could be identified in the urine of II–1 (ref. 9). It is noteworthy that renal biopsy specimens obtained percutaneously from II–1 and II–2 failed to reveal abnormal iron deposition in the renal parenchyma as might result with chronic hæmoglobinæmia.

These results indicate that genetically determined haptoglobin depression is not invariably associated with the Hp2^{m}–1 phenotype in the American Negro. Although the mechanisms involved are unclear, they would appear to be discrete from the *Hp*2^{m} allele, and as yet manifest only in the presence of the *Hp*^{1} allele.

HISTOLOGY

Enzymatic Maturation of Skeletal Muscle

IN adult human and mammalian skeletal muscle there are two types of fibre. One is rich in oxidative enzymes and poor in phosphorylase and usually of smaller diameter, while the other group is rich in phosphorylase and poor in the oxidative enzymes[1]. In two cases of benign congenital hypotonia[2] and in a case of central-core disease[3] it was noted that all the fibres had a uniform enzyme activity.

The lack of differentiation of the muscle fibres in some diseases may represent a failure of maturation of the muscle. The investigations recorded here were undertaken to determine whether the muscle is already differentiated at birth.

Human muscle was obtained at autopsy from the gastrocnemius and quadriceps of full-term infants who had died within 24 h of birth. Muscle was taken from the limbs and trunks of freshly killed animals (guinea pig, rabbit, rat and hamster) less than 24 h old.

All specimens were mounted in a transverse plane on a slice of cork, rapidly frozen in liquid air and approximately 5μ sections were cut on a cold microtome at −25° C. Sections were mounted on coverslips and the following enzymes investigated: phosphorylase, DPN diaphorase, DPN-linked lactate dehydrogenase, and adenosine triphosphatase.

In full-term human infants the muscle was already differentiated at birth. The muscle fibres were much smaller than in adult muscle and were rounded in transverse section. They were arranged in bundles. The fibres rich in phosphorylase were of slightly greater diameter than those rich in the oxidative enzymes. The adenosine triphosphatase activity also showed variation, and in individual fibres it correlated with the phosphorylase activity. In autopsy muscle the adenosine triphosphatase and oxidative enzymes gave consistently positive results, but the phosphorylase was sometimes negative.

In the guinea pig, rabbit and hamster there was also differentiation of the muscle fibres at birth. This was most striking in the guinea pig where the fibres were polygonal in shape and arranged in bundles and resembled adult muscle. In the rabbit and hamster the differentiation was less marked, and the fibres tended to be rounded and were not so clearly grouped into bundles.

In the rat the fibres were not differentiated at birth. The investigation was then extended to include rats aged 1–14 days. Differentiation usually occurred between 7 and 10 days of age. This varied from one group of muscles to another, and in some muscles was noticeable with the adenosine triphosphatase reaction before the others. In some instances, particularly in the abdominal muscles, there was evidence of focal differentiation at 2 or 3 days of age. The rate of differentiation also seemed to be influenced by nutrition and general growth since rats from smaller litters tended to be larger and more mature and their muscle showed earlier maturation. By 14 days the muscle resembled that of the guinea pig at birth and appeared to have reached full maturity.

The difference in maturation in these animals may be partly accounted for by their length of gestation and their degree of general maturity at birth. The guinea pig with a 68-day gestation period has a more mature fur at birth and is much more mobile than the others. The rabbit (30–32 days' gestation) has a better-developed fur and is more active than the rat (gestation 21 days). The hamster, although having a shorter gestation (16–19 days) than the rat, also appears to be more active at birth, and its fur develops more rapidly. No direct comparison can be drawn in humans.

PATHOLOGY

Electrophoretic Mobility of Human Tumour Cells

IT has been suggested that one of the characteristics of embryonal[1], proliferating[2], or neoplastic[3] mammalian cells is the presence of a high surface negative charge, as measured by cell electrophoresis. Data on fresh human tumour cells have not been available, however, except for studies of leukæmic cells[4,5]. The present investigation was designed to accumulate cell electrophoretic mobilities from a variety of fresh human tumour tissues.

Human tumour tissue was available from surgically excised specimens; in all instances the neoplastic tissue was dissected immediately following removal from the patient. Care was taken to select tumour tissue which was completely viable and without evidence of cyst formation, degeneration, hæmorrhage, inflammation or ulceration; it was selected to avoid adjacent normal tissues. The tumour tissue fragments thus obtained were placed in cold, sterile, isotonic saline solution within 5–10 min after removal from the patient; in some instances specimens of corresponding normal tissue from the surgical specimen were similarly treated. The tissue fragments were then washed with cold isotonic saline, followed by fine mechanical separation with eye scissors. These fragments, suspended in saline, were then passed through either a small Latapie mill or graded sieves. Sedimented tissue debris and cell clumps were discarded. The cell suspension was then suspended in sucrose–phosphate buffer.

The electrophoretic apparatus and general technique was similar to that described by Eylar *et al.*[6]. The rect-

Mean negative mobilities, corrected to viscosity of water at 25° C., are expressed as μ/sec/V/cm. S.D. < 0.05.

angular cell, placed in a thermostat at 25 ± 0·01° C, was in the lateral position. Readings were taken at either the first or second stationary levels. The current was 4·0 m.amp, and the electrodes were silver, silver chloride. The buffer contained 0·201 M sucrose, 0·012 M disodium hydrogen phosphate, 0·003 M sodium dihydrogen phosphate and 0·0441 M sodium chloride; the pH was 7·0 and the ionic strength 0·083. An average of 20 or more mobilities was determined on each specimen. The apparatus was checked by daily runs of human red cells; in this apparatus, human red cells have an average negative mobility of 1·64 μ/sec/V/cm and Ehrlich ascites cells 1·21 μ/sec/V/cm.

The results (Table 1) show that epithelial malignant tumour cells (specimens 1–8) do not reveal a particularly high (negative) electrophoretic mobility; indeed, specimens 7 and 8 suggest that the tumour cell mobilities may be lower than corresponding normal tissue cells. On the other hand, connective tissue tumours (specimens 9–13) exhibit a fairly high mobility. The blast cell leukæmia buffy coat contained two cell populations according to size and electrophoretic mobilities.

The significance of these results is, at present, obscure. Present investigations in this laboratory are being carried out to elucidate the nature of tumour cell surface charges by enzyme treatment (neuraminidase, hyaluronidase), anion blocking (organic bases, polyvalent cations) and cation blocking.

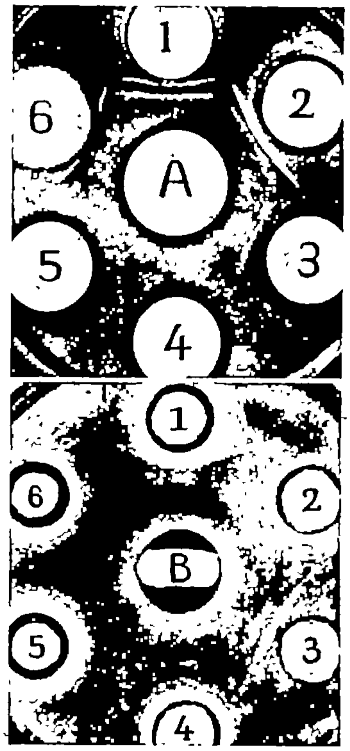
Production of a Highly Tissue-specific Antiserum against a Particular Sub-fraction separated from Kidney Microsomes

Immunological studies on tissue- or organ-specificity have been seriously handicapped by difficulty in obtaining an antiserum highly specific to a particular tissue or organ. Though the microsomes of several organs such as liver and kidney are known as the sites of so-called 'organ-specific' antigens[1], the antigenic composition of the microsomes is extremely complex[2]. They usually contain a number of 'non-specific' components, besides 'organ-specific' ones[3]. Recently, one of us[4] has reported that the deoxycholate extracts of kidney microsomes can be separated into several immunologically distinct sub-fractions, one of which contains 'kidney-specific' components. In the present communication the antibody-patterns of antisera produced against the separated sub-fractions will be described.



Figs. 1 and 2 Central wells: *A*, antiserum against *SF* : serum against *SF* 45. Peripheral wells: 1, *D*-fraction of kidney microsomes; 2, *SF* 20 of kidney microsomes; 3, *SF* 45 of kidney microsomes; 4, *SF* 80 of kidney microsomes; 5, *S*-fraction of kidney homogenates; 6, *D*-fraction of liver microsomes

The microsomal fraction isolated from chicken kidneys was treated with 0·5 per cent deoxycholate and was centrifuged at 105,000*g* for 90 min. The supernatant thus obtained (*D*-fraction) was separated into three sub-fractions by means of the fractional precipitation with ammonium sulphate after much the same procedures as previously given[4] though somewhat modified. These were: (1) the proteins precipitated between 10 and 20 per cent saturation of ammonium sulphate (sub-fraction 20); (2) the precipitate between 25 and 45 per cent saturation (sub-fraction 45); (3) the precipitate between 60 and 80 per cent saturation. Preliminary results on the chemical composition of each sub-fraction indicate that sub-fraction 20 and sub-fraction 45 contain most lipids of the microsomes, probably representing the materials of the membrane of endoplasmic reticulum, while lipid-poor sub-fraction 80 may be the content of the microsomal vesicles[4].

Each sub-fraction, after being dissolved with water and dialysed against it, was injected into rabbits with adjuvant technique. Ring precipitin tests with different dilutions of both test-antigens and the antisera revealed that each antiserum contains relatively high concentrations of the

Table 1

D-fraction of liver	40	20	160	8	4	64
Sub-fraction 20	320	80	—	64	8	—
Sub-fraction 45	80	640	40	8	64	32
Sub-fraction 80	20	80	640	1	8	128

* Each undiluted test-antigen contains *c*. 1·0–1·5 mg protein/ml.
† Each test-antigen contains *c*. 30–50 μg/protein/ml.

antibodies against the homologous antigen (Table 1). The results were well confirmed by double diffusion test in agar. Antigenic component to cause a strong line in reaction with the antiserum against sub-fraction 20 is commonly distributed to *D*-fractions of both kidney and liver, but is scarcely detectable in sub-fractions 45 and 80 as well as in the unsedimentable fraction (cell sap, sub-fraction) of the kidney homogenates (Fig. 1). Therefore, this type of antisera can be said as highly 'fraction-specific' but not 'kidney-specific'. The antiserum against sub-fraction 45 is highly 'kidney-specific'. In reaction with sub-fraction 45 and *D*-fraction of kidney, it produces a strong precipitate, identical line to which is scarcely perceptible against other test-antigens prepared from the homologous and the heterologous organs such as liver and lung (Fig. 2). Besides, this antiserum is contaminated with several minor antibodies to produce a few weak lines, some of which occur also against sub-fraction 20 or sub-fraction 80. The antiserum against sub-fraction 80 has quite different antibodies from those contained in the foregoing two types of antisera. Strong lines produced by anti-sub-fraction 80 against the homologous antigen are identical to those developed against *D*- and sub-fractions of both homologous and heterologous organs. The antibodies contained in anti-sub-fraction 80 may be predominantly directed against such components that are neither 'microsome-specific' nor 'kidney-specific'.

The antiserum against sub-fraction 45 was conjugated with rhodamine sulphate[5] and used as a histochemical reagent to stain the freshly frozen sections of kidney, liver and lung of embryonic chickens (16–17 days) and newly hatched ones. Only the epithelial cells of the kidney tubuli bind the conjugated antiserum.

Since these antisera, the antibody patterns of which were briefly described here, make it possible to detect particular molecular groups contained in kidney microsomes, they may be valuable tools to follow sub-cellular or molecular changes occurring in the course of embryonic differentiation as well as of carcinogenesis of kidney.

Age Changes of the Thymus in Two High-leukaemia Strains of Mice, *SL* and *AKR*, and in their F_1 Hybrids

Metcalf[1] has shown that the thymus from both sexes of the high-leukaemia strain of mice, strain *AKR*, greatly exceeds in weight that from the low-leukaemia strain *C3H* mice. Furthermore, it was noted that the weights of the *AKR* thymus show a pronounced sex difference, the thymus of females being much heavier than that of males. Arnesen[2] has also observed that the weights of the thymus from strain *AKR* exceed those from the low-leukaemia strain *WLO*. He also pointed out that the adrenal cortex in strain *AKR* contains a smaller amount of lipid-staining material as compared with the tissue of the latter strain.

In the present work, two high-leukaemia strains *AKR* and *SL* and their F_1 hybrid mice bred in our laboratory were used. The origin of these two inbred strains of mice has already been described[3].

A comparative study of the pathology of leukaemia in the two high-leukaemia strains, *AKR* and *SL* (ref. 3), showed that the majority of cases of lymphoid tumours in *AKR* were of thymic origin, whereas in strain *SL* spontaneous leukaemic tumours of thymic origin were not observed. The tumours more frequently originated in the mesenteric lymph node.

All experimental animals were separated according to sex and maintained in an air-conditioned room kept at approximately 23° C with free access to 'Oriental Compressed Diet *CMF*' and water, and were not subjected to any type of treatment. The animals were killed with ether at designated intervals after birth and the thymus, spleen, and mesenteric lymph node were dissected free of extraneous tissues and weighed on a torsion balance. The kidney and liver were also weighed. After weighing, all tissues were fixed in 10 per cent formalin, embedded in paraffin, and stained with hæmatoxylin and eosin for histological study. All animals included in the tabulation were confirmed to be free from leukæmia or other significant diseases. Each age group of either sex consisted of more than five mice.

The maximum weight of the thymus was reached in strain *AKR* at sixty days after birth in the females and at thirty days in the males. In strain *SL*, the age for attaining maximum thymus weight was somewhat earlier than in strain *AKR* and was at forty days in the females and at twenty days in the males (Fig. 1). It was of particular interest to note that sexual maturity in females, as determined by the vaginal smear method, is reached earlier in strain *SL* (thirty-four days of age) than in strain *AKR* (thirty-eight days of age) and that the age of onset of involution of the thymus was well correlated with the time of sexual maturity. In agreement with Metcalf's observations, a pronounced sex difference in the thymus weight was clearly demonstrated in the two strains of mice: the thymus glands of females weighed much more than those of males. A significant sex difference (examined using Student's *t* series at the 0·05 level) was noted from forty days after birth in strain *AKR* and from thirty days in strain *SL*. Although the results obtained with F_1 hybrid mice are incomplete, the shape of the thymus-growth curves was similar to that of the parental strains. From Fig. 1, it is also evident that the *AKR* thymus is greatly hyperplastic when compared with that of strain *SL* of the same sex.

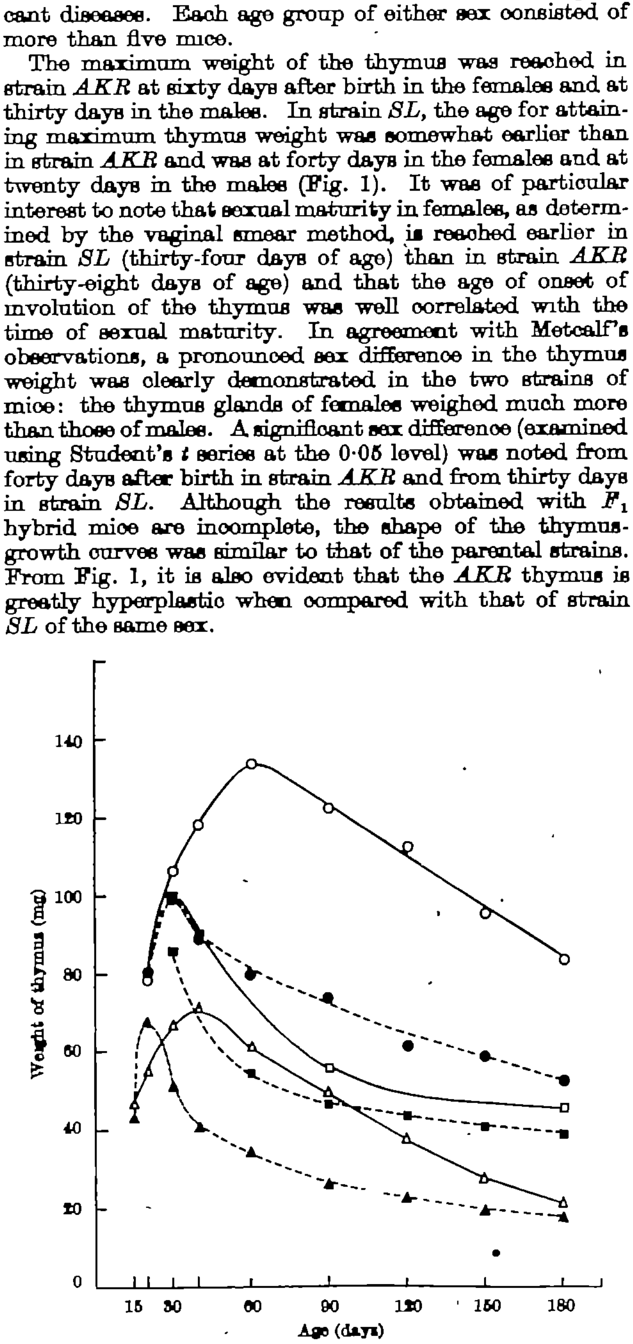

Fig. 1. Changes in weight of the thymus with age. ● - - - ●, *AKR*, male; ▲ - - - ▲, *SL*, male, ■ - - - ■, (*AKR* × *SL*)F_1, male. Continuous lines and open symbols represent corresponding females

Table 1. AVERAGE PROPORTION OF THE MEDULLA IN THE THYMUS

Strain	Male Age (months) 1	 6	Female Age (months) 1	 6
AKR	16·5% (5)*	21·2 (8)	14·2 (6)	27·7 (8)
SL	28·5 (7)	38·2 (6)	23·6 (6)	44·1 (6)
(*AKR* × *SL*) F_1	23·0 (6)	28·5 (5)	22·3 (7)	32·3 (5)

* Total number examined.

Sections of the thymus were projected on white paper and the outlines of the cortex and the medulla were traced. The percentage of the area occupied by the medulla in the thymus was calculated. The results obtained at one and six months of age are presented in Table 1. The relative size of the medulla seems to increase with advancing age. It was also interesting to find a difference in histology of the thymus between the two strains examined: the relative size of the medulla being larger in strain *SL* than in *AKR*, and the values obtained in the F_1 hybrid mice were intermediate between those of the two parental strains.

A detailed study of the histology of the lymphoid tissues from the two strains of mice is now in progress, to investigate preleukæmic lesions and the earliest stage of leukæmic proliferation in the thymus and/or other lymphoid tissues.

Encephalitogenic Factor in Experimental 'Allergic' Encephalomyelitis

SEVERAL attempts to isolate purified encephalitogenic factor(s) capable of producing experimental 'allergic' encephalomyelitis (with Freund's adjuvants) have been reported[1-5]. Recently, Kies, Gordon, Laatsch and Alvord[6] were successful in obtaining a derivative from guinea pig brain active in doses of 1–2 μg; and Robertson *et al.*[7] obtained a preparation which showed "high . . . activity even at five gamma doses".

A material capable of producing disease in twelve out of twelve guinea pigs (about 500 g weight) when 1 μg was injected with Freund's adjuvants has been isolated from fresh human post-mortem brain. It was obtained by a method differing from that of Kies *et al.*[3] only in so far as special precautions were taken throughout to maintain an acid *p*H (refs. 2–5). On passing through a 'Sephadex *G*100' column this material gave five components, most of the activity being contained in the second (largest) fraction. Electrophoretic examination showed that the original material comprised a major and a minor moiety migrating towards the cathode at *p*H 5. The most active eluate from the Sephadex column migrated as a single component in the same direction, provided that the *p*H was again maintained at 5·0. If the *p*H were altered to 9·0 then this purified material showed one major and five minor bands.

An analytical ultracentrifuge analysis, kindly carried out by Dr. R. A. Kekwick of the Lister Institute, showed only one component in both the crude and the column-purified encephalitogenic material. It seems probable that relatively small molecules (20,000–50,000 mol. wt.) are involved.

The non-specific antigens shared by brain with various other tissues[8,9] can still be demonstrated in both the crude and the purified encephalitogenic factor by the Ouchterlony plate method. Obviously then, despite the high activity of the final material, non-active contaminant yet remains.

An attempt has been made to demonstrate circulating antibody to the encephalitogenic factor both in experimental 'allergic' encephalomyelitis of guinea pigs and in human multiple sclerosis cases by the tanned red blood cell technique. So far, no statistically significant difference from controls has been demonstrated in either case. Nor have serial estimations of the serum titre of encephalitogenic factor-antibody in animals which developed experimental 'allergic' encephalomyelitis after the inoculation of freeze-dried brain plus Freund's adjuvants demonstrated a rise in antibody level.

Since the development of experimental 'allergic' encephalomyelitis has in general been linked with the evolution of a delayed tuberculin type sensitivity to the brain used as antigen, skin sensitivity to encephalitogenic factor has been tested in animals suffering from the disease. This sensitivity has been compared with that developed to the saline supernate from fresh brain emulsion, known to be non-encephalitogenic. While guinea pigs suffering from experimental 'allergic' encephalomyelitis (induced by freeze-dried brain plus Freund's adjuvants) show definite sensitivity to encephalitogenic factor ($P < 0·001$), they do so also to the inactive supernate referred to here ($P < 0·001$). Moreover, sensitivity of such animals to supernate is greater than it is to encephalitogenic factor ($P < 0·05$–$0·02$). These results suggest that many of the skin hypersensitivity observations hitherto published may relate to material which is non-encephalitogenic.

RADIOBIOLOGY

Effect of Fluoroacetate on Uptake of Yttrium-91 in Rabbits

STUDIES of yttrium-binding by bone powder and bone extracts have indicated that the presence of citrate might explain the uptake of yttrium-91 in bone[1]. The experiments recorded here were undertaken to determine whether the citrate content of tissues could be correlated with uptake of yttrium, and for this purpose the uptake of yttrium in the soft tissue of the rabbit was investigated after giving sodium fluoroacetate to the animal prior to the yttrium.

Several workers[2-4] have examined citrate accumulation in the soft tissues of rats at various times after injection with non-lethal doses of fluoroacetate. They were able to observe a 10- to 20-fold increase in concentration of citrate in tissues such as heart, spleen and kidney, but no significant increase in bone[4,5]. Similar investigations of citrate accumulation in the soft tissues of rabbits have not been reported. In my experiments Dutch rabbits received intraperitoneal injections of sodium fluoroacetate; the dose ranged from 0·1 mg/kg to 1·0 mg/kg body-weight.

The rabbits either died or were killed by anaesthetizing and cutting the jugular vein, and the citrate content of the spleen, liver, kidneys and heart was analysed by the method of Taylor[6]. The results are shown in Table 1. Whereas in the rat all the soft tissues except liver show elevated citrate-levels, in the rabbit the heart was the only organ in which a large increase in citrate content could be demonstrated.

Table 1. CITRATE-LEVELS IN SOFT TISSUES OF YOUNG RABBITS AFTER INTRAPERITONEAL INJECTIONS OF FLUOROACETATE

Dose (mg/kg)	Liver	Spleen	Kidney	Heart	Remarks

0·5	30	70	70	680	Died after 1½ h
1·0	30	50	100	300	Died after 1 h

In the experiments where yttrium was injected after giving fluoroacetate, a series of 5 fluoroacetate injections at half-hourly intervals (total dose 0·5 mg/kg body-weight) were given prior to intravenous injection of carrier-free $^{91}YCl_3$ (dose 45–80 μc./kg body-weight). The animals were killed 10 min and 1 h after receiving $^{91}YCl_3$, and the tissues were analysed for citrate and yttrium-91 content. Control rabbits received saline injections in place of fluoroacetate. Although at least a 6-fold increase in citrate concentration could be demonstrated in the heart, there was no similar increase in yttrium-91 content. The content of yttrium-91 in the liver, kidney, heart, spleen, blood, femur and tibia were examined and at both time intervals there was good agreement between the values for the control rabbits and those receiving fluoroacetate injections. It was therefore concluded that in soft tissues there was no correlation between yttrium uptake and citrate content. In bone, however, under normal conditions, this argument may not hold, since the citrate may be present in a different form—as a polypeptide complex[7], or as a calcium salt[8,9].

I thank Dr. Janet Vaughan and Dr. C. A. Pasternak for their advice.

Change of Phytol into Chlorophyll *a* in *Chlorella vulgaris*

Chlorella vulgaris was grown in sterile wort agar under constant illumination. When the alga had reached maximum growth it was collected and pooled using a sterile solution[1].

After filtration and several washings the plants were resuspended in the same solution used for washing to which 2-^{14}C-glycine (specific activity 5·69 mc./mM (Radiochemical Centre, Amersham, England)) were also added. About 9·2 g wet algae, and 260 ml. of the solution containing 12 μc. of labelled glycine were placed quickly in each of 7 Erlenmeyer flasks. The flasks were whisked from time to time. Incubation was stopped after the following periods: 1·5, 3·0, 4·5, 6·0, 8·0, 12·0, 21·0 h. The cells were collected by centrifugation, washed alternately with saline and with saline plus 1 per cent of inactive glycine and stored in deep freeze (−50° C) until the chlorophyll could be extracted, following the procedure described by Strain and Manning[2]. The separated chlorophyll *a* was again chromatographed on cellulose (solvent benzine + 0·5 per cent propanol). The prepared chlorophyll had an absorbance ratio at 660 mμ and 428 mμ of 1·27 ± 0·02. Amounts of chlorophyll, spectrophotometrically quantitized, were added with carbon carrier and their activity measured using the gas counting technique[3]. Then the pheophorbide was prepared as outlined in ref. 4, and assayed again for its specific radioactivity in the same way as that used for the chlorophyll. The molar extinction coefficients used were: 8·80 × 10^4, and 5·27 × 10^4 for pheophorbide[5,6].

Table 1

Exp.	Material	Incubation time (h) 1·5	3·0	4·5	6·0	8·0	12·0	21·0
(1)	Chlorophyll	264	1,100	520	690	5,280	824	1,150
	Pheophorbide	90	245	262	393	505	510	512
	Phytol*	174	855	258	297	4,775	314	638
(2)	Chlorophyll	223	247	136	220	241	231	308
	Pheophorbide	33	52	70	71	100	103	98
	Phytol*	190	195	66	158	141	128	210

Specific activity in disintegrations/(min × μM) at different incubation times (relative error < 3–4 per cent).

* Calculated from those of chlorophyll and pheophorbide.

The results of two experiments are presented in Table 1. It can be seen that the carbon-14 incorporated in the second experiment is smaller and that the relative heights of the two peaks are also different; but the specific activities are the same. We believe the age of algal culture explains this: the algae used for the first experiment were collected after two weeks and those of the second experiment after one month. It must be remembered that the metabolic activity of chloroplasts changes with the age The specific activity of chlorophyll *a* reaches two maxima at about 2·5 h and 8 h, and at the end of the incubation it is increasing again. The specific activity of pheophorbide increases closely according to an exponential law, and reaches a saturation value at about 8 h of incubation. Therefore, the activity peaks of chlorophyll are due to the phytol.

These results may be explained by the following hypothesis:

(1) The specific activity of glycine decreases during the course of the experiment: the specific activity of pheophorbide reaches a constant value at about 8 h incubation and it was shown that the *Chlorella* could be cultivated for 5–6 days, at least, in the solution used. Therefore, if the specific activity of pheophorbide does not increase after 8 h, it must be argued that the glycine cannot be labelled at this time.

(2) The glycine is significantly converted in other compounds: we found the phytol to be radioactive. But we have also direct proof of this fact. In the second experiment an eighth sample was made, from which, after 20 min incubation, the dinitrophenylhydrazones of pyruvic and ketoglutaric acids were isolated, separated from themselves, and assayed for their specific activities. The activity found in these two compounds was about 5 per cent of that of the 2-^{14}C-glycine used in the experiment.

(3) There is an exchange reaction between the free phytol and that linked to chlorophyll: we found that the specific activity of phytol reaches a maximum value and then decays, contrary to pheophorbide. It can be demonstrated that the specific activities of precursor and product have the same values when the specific activity of the product had reached its maximum[4]. Obviously, if a product has more than one precursor, the specific activity of the product must have more than one maximum, because this relation must be verified for every precursor. The results

show that there are, at least, three sources of carbon-14 coming from 2-^{14}C-glycine for the phytol.

BIOLOGY

A Germplasm-transmitted Alteration of Histocompatibility in the Progeny of Homograft Tolerant Mice

The *in vivo* co-existence of cells of two genotypes achieved in the state of actively acquired tolerance inspired this investigation to determine if any detectable changes occurred in progeny of tolerant mice secondary to the exposure of maturing germ cells to a chimæric environment.

A litter of 5 C_3H mice was injected intravenously during the first 24 h of extra-uterine life with 2–4 × 10^6 nucleated cells from the spleen of an A strain adult male donor to produce tolerance after the model of Billingham, Brent and Medawar[1]. When they reached 30 days of age, the 4 animals, weaned from the injected litter, were grafted with full-thickness abdominal skin measuring 1·5 × 2 cm from A male donors. These grafts were placed on the dorsum of host mice, rotated 180°, and observed for gross signs of acceptance or rejection. At 60 days post-injection, the litter of 2 males and 2 females showed 1 male and the 2 females bearing healthy appearing A strain allogeneic grafts. The tolerant male was then placed in a breeding cage with $(A \times C_3H)F_1$ hybrid female mice and afterwards produced 7 litters of the back-cross progeny hereafter known as $ZBC_{S_1}(C_3H_{\text{tolerant}}\ A♂ \times (A \times C_3H)F_1 ♀)$. Non-injected C_3H males bred with $(A \times C_3H)F_1$ hybrid females produced the back-cross control group of ZBC mice and breeding between $(A \times C_3H)F_1$ hybrid males and females produced the $(A \times C_3H)F_2$ hybrid. Additional control groups were formed by using inbred C_3H, A, and $(A \times C_3H)F_1$ hybrid mice. An $(A \times C_3H)F_1$ hybrid breeding female in our colony spontaneously developed a mammary adenocarcinoma which was used with an 18th transplant generation A strain mammary adenocarcinoma to test the acceptance by the various groups of mice. The latter tumour had been transplanted among A strain animals only, during its course of development, to avoid any of the changes in histocompatibility known to occur in tumours grown in donor and host of different genotypes previously described by Barrett and Deringer[2]. A cellular suspension of each neoplasm was prepared by mechanical homogenization of 2 g of tumour in 10 c.c. of saline and was then diluted to a final concentration of 20–25 × 10^7 nucleated cells per c.c. All test animals were injected with 0·1 c.c. of this suspension subcutaneously, injecting the $(A \times C_3H)F_1$ hybrid tumour in the dorsal neck region and the A tumour in the right inguinal area. The animals were checked weekly for the presence of tumour until time of death. The results are summarized in Table 1.

The back-cross population bred from the tolerant male and $(A \times C_3H)F_1$ hybrid female showed an $(A \times C_3H)F_1$ hybrid tumour incidence at time of death of 91·3 per cent although 5 weeks after tumour inoculation there were 45 nodules palpable in the 46 ZBC_{S_1} mice and at 7 weeks there were 43 palpable growths. There were 13 palpable A strain tumour nodules at 5 weeks of growth, 17 at 7 weeks and 14 large tumour masses at time of death. The animals succumbed to their malignancy between 6–14 weeks following injection. In the other groups of animals, no instance of growth of tumour followed by regression was noted. The incidence of the A and $(A \times C_3H)F_1$ hybrid neoplasms in the A, C_3H, $(A \times C_3H)F_1$, ZBC, and $(A \times C_3H)F_2$ groups followed the expectations of susceptibility determined by multiple dominant histocompatibility factors which are formulated in the theory of the genetic basis of transplantation[3,4]. The acceptance of both A and $(A \times C_3H)F_1$ hybrid tumour in the ZBC_{S_1} mice, however, compared with the ZBC mice can be seen to be significantly different.

The explanation for an almost uniform acceptance of the hybrid tumour by the ZBC_{S_1} and only a 30 per cent rate of take of the A tumour is not clear. If the inherited change in the back-cross progeny of the tolerant mouse involved the acquisition of an A complex of antigens it would be expected that the A tumour be accepted with the same incidence as the $(A \times C_3H)F_1$ hybrid tumour. The change in the progeny, however, may involve the failure of response to A antigen in the hybrid dose while the tumour from the inbred animal presented enough of an antigenic stimulus to prevent its acceptance in some of the animals.

Owen[5] and Stone *et al.*[6] have demonstrated that the progeny of chimæric bulls possessed blood cells of one genotype only and thus further evidenced the cattle chimerism as a phenomenon of transplantation of hæmatopoietic tissue during pre-natal existence. It is not known, however, whether these animals would have responded with the production of agglutinins after challenge with cells of the non-transmitted blood type of their sire[7]. Further study is in progress to determine the nature of the change described in this report. The length of its heritability would give information whether the germ cells of the tolerant animal are functioning with a replicating chemical messenger of non-genetic material which renders a degree of tolerance to its cells until diluted out through successive cell divisions. The recent demonstration in *Drosophila* by Fox[8] of a one generation modification of a specific type protein in progeny lacking the appropriate chromosomal segment, but present in their female parent, may have a mechanism parallel to the alteration of histocompatibility seen in these experiments.

Elucidation of the nature of the tolerant state as well as the study of other types of cellular changes secondary to

Table 1. Allogeneic Tumour Susceptibility in Back-cross Progeny of C_3H Tolerant A ♂

No. of animals	Strain host	Strain Tumour donor	Takes	%	Strain Tumour donor	Takes	%
14	A	$(A \times C_3H)F_1$	0	0	A	14	100
8	C_3H	$(A \times C_3H)F_1$	0	0	A	0	0
9	$(A \times C_3H)F_1$	$(A \times C_3H)F_1$	9	100	A	9	100
31	$(A \times C_3H)F_2$	$(A \times C_3H)F_1$	2	6·5	A	5	16·1
39	ZBC*	$(A \times C_3H)F_1$	3	7·7	A	0	0
46	ZBC_{S_1}†	$(A \times C_3H)F_1$	42	91·3	A	14	30·4

* $ZBC = C_3H$ ♂ × $(A \times C_3H)F_1$ hybrid ♀

† $ZBC_{S_1} = C_3H_{\text{Tolerant}}\ A$♂ × $(A \times C_3H)F_1$ hybrid ♀.

All animals (45–90 days old) were inoculated subcutaneously with 2·0–2·5 × 10^7 tumour cells in saline suspension. The $(A \times C_3H)F_1$ hybrid tumour was a spontaneous neoplasm and the A tumour was in its 18th transplant generation.

exposure with allogeneic cells may be possible with this type of system. In addition to determining the length and specificity of the change, it will be important to determine whether the alteration noted involves the transfer of genetic material, the precursor system of antigenic specificity or, more likely, whether these animals have an alteration in the cellular system involved in the recognition of *A* strain antigens.

Rumen Function in the Camel

IN May 1962, samples of strained rumen contents obtained from 25 camels in the Alice Springs area of Central Australia were made available for analysis. The animals had all been born in the area (the last importation of camels into Australia was made in 1886)[1]. The area had been suffering from drought conditions for the previous seven years, but the camels were in reasonable physical condition and apparently reproducing satisfactorily. British breeds of cattle are normally grazed in the area; but their numbers had been greatly reduced during the drought and many of the survivors were in poor condition.

The *p*H of the rumen contents were determined in the field before straining through cheese cloth, and the fluid was preserved with mercuric chloride for transport to the laboratory.

Other chemical methods were as follows: total nitrogen—Kjeldahl technique using selenium as the catalyst; total volatile fatty acid—steam distillation through a Markham still after acidification with sulphuric acid[2]; proportions of volatile fatty acids—gas chromatographic technique of James and Martin[3].

Although a full botanical analysis of the contents of the rumina was not made, leaves of *Eucalyptus gamophylla* predominated and were associated with small quantities of *Acacia aneura* and *Acacia rempeura*. A diet of this composition would be low in protein as eucalyptus leaves contain approximately 1 per cent nitrogen and acacia leaves 1·5 per cent nitrogen[4].

Ruminants re-cycle nitrogen into the rumen from the plasma via the saliva and by diffusion through the rumen wall[5,6]. Schmidt-Nielsen *et al.*[7] have shown that on a low nitrogen intake camels are very efficient at conserving body nitrogen by limiting urea excretion in the urine, and if re-cycling also occurs in the camel these mechanisms would result in higher rumen nitrogen and more active fermentation than would otherwise be possible.

The results which were obtained are summarized in Table 1.

Table 1. CHEMICAL CONSTITUENTS OF THE RUMEN FLUID

	Concentration	*S.D.*	Range	No. of samples
Volatile fatty acids (mM/l.)	133·8	25·0	98·1–185·0	25
Total nitrogen (mg/l.)	726	254	360–1,230	23
*p*H	6·4	0·3	4·8–6·8	25

Proportion of volatile fatty acids (per cent)

No. of samples	Acetic	*S.D.*	Propionic	*S.D.*	Butyric and higher	*S.D.*
10	77·1	4·6	16·4	2·3	6·5	3·8

Table 1 shows that the rumen contents were low in nitrogen and high in volatile fatty acids. The latter does not necessarily mean that the rate of fermentation of the diet was rapid. The rumen contents were relatively dry and apparently similar to those described by Schmidt-Nielsen *et al.*[8]. Camels do not have rumen papillæ[9]. Both these factors could slow down the rate of absorption of volatile fatty acid from the rumen.

The proportions of volatile fatty acids are similar to those produced in the rumina of sheep or cattle by any high roughage low nitrogen diet[10], and the microbial population of the rumen had a similar morphological appearance to that present in sheep on low nitrogen diets, but no protozoa were seen.

Camels graze a wider range of top feed than cattle because of their greater height, and the evidence presented here suggests that the camel can maintain quite satisfactory rumen function on this diet. Cattle can be forced to eat eucalyptus leaves under serious drought conditions, but even if the top feed eaten by camels were made available to them it would not constitute a suitable maintenance ration.

Differences in the rate of passage of food through the alimentary tracts of camels and cattle could be of interest particularly in view of the results presented here and the fact that the camel does not have an omasum[11].

The samples were obtained and processed in the field by Mr. A. J. Mackenzie, leader of the University of New England Exploration Society's Expedition to Central Australia. This work was supported by research grants from the Australian Wool Research Committee and the University of New England.

Immunogenic Activity of the Larval Stages of *Haemonchus placei*

IT has been shown in calves which have experienced a substantial initial infection of *H. placei* that they develop a high level of immunity to further larval challenges and that the removal of a mature adult burden with phenothiazine therapy appears to delay the development of the immunity[1,2]. More recent work where calves had mature *H. placei* surgically implanted into the abomasum indicated that the implant conferred no immunity to the recipient calves to a challenge with 10,000 infective larvæ[3].

The development of the anthelmintic 'Neguvon', which is highly effective against all parasitic stages of *H. placei*[4], has made it possible to stop an infection at selected stages. In the present investigation, 'Neguvon' was used to terminate artificial infestations in calves on the twelfth day when the moult from the 4th to 5th stage occurs. Thirty calves were reared parasite free and infected with 3rd-stage infective *H. placei* larvæ to compare the immunity produced to a challenge of 10,000 infective 3rd-stage larvæ, by two infections of 3rd and 4th stages and

Table 1. DESIGN OF EXPERIMENT

Group	No. of calves	Treatment on day 0	12th	33rd	45th	66th	108th
1	7	10,000 3rd-stage larvæ orally	'Neguvon' treatment	10,000 3rd-stage larvæ orally	'Neguvon' treatment	10,000 3rd-stage larvæ orally	Killed
2	7					10,000 3rd-stage larvæ orally	Killed
3	3	10,000 3rd-stage larvæ orally		10,000 3rd-stage larvæ orally		10,000 3rd-stage larvæ orally	Killed

two infections of 3rd, 4th and 5th stages. Details of the treatments accorded to the three main groups of calves in the experiment are shown in Table 1. A further six groups of calves were used to establish the infectivity of the larval batches used and the efficacy of the treatment with 'Neguvon'.

Table 2. MEAN POST-MORTEM WORM COUNTS

Group	4th-stage larvæ	5th-stage adults	Total worm burden
1	157	2,198	2,355
2	57	2,374	2,431
3	33	10	43

The mean post-mortem worm counts for the three groups are given in Table 2. Control groups showed that at the time of treatment with 'Neguvon', on the twelfth day post-infection, the larvæ had developed to the late 4th stage or very early 5th stage. The results indicated that little effect on the course of a challenge infection, other than slight delayed development, resulted from the host's previous experience of a double infection consisting mainly of the 3rd and 4th stages of the parasite, while a continuance of the original infection to include the patent 5th stage produces a high level of immunity. These and previous results[3] appear to emphasize the importance of the early 5th stage of *H. placei* in the production of immunity in the bovine; but further work is necessary to consider the effects of time, length of infection, larval moults and other possible immune stimuli.

Energy Utilization of Poor Quality Roughage by Water-deprived Steers

RECENT, but as yet unpublished, work by Livingston, Payne and Friend[1] and Payne and Livingston[2] has shown that cattle are able to reduce their nitrogen output on a low nitrogen intake treatment when water consumption is either voluntarily or compulsorily restricted. At the suggestion of these authors it was decided to extend this work to make a preliminary examination of the energy as well as the nitrogen balance of water-deprived animals.

Table 1

$$\frac{\text{Energy retention (cal/24 h)}}{\text{Digested energy (cal/24 h)}} \times 100$$

	Ayrshire 1	Ayrshire 2	Boran 1	Boran 2
12 per cent crude protein and *ad lib.* water	39·5	43·1	39 1	32·5
4 per cent crude protein and *ad lib.* water	−18·7	−19·3	−4 9	−19·7
4 per cent crude protein and water deprivation	1·7	1·0	−1·8	2 1

Two sets of identical steer twins, one *Bos taurus* (Ayrshire) and the other *Bos indicus* (Boran), were used in this experiment. The rations, which were fed to all four animals, were: (1) 12 per cent crude protein ration of hay and concentrates with *ad lib.* water; (2) 4 per cent crude protein ration of hay to appetite with *ad lib.* water; (3) 4 per cent crude protein ration of hay to appetite with 96 h water deprivation.

A change-over period of three weeks was allowed between the different rations. Oxygen consumption, carbon dioxide output and methane production were measured for each animal on each ration at 20° C and 50 per cent relative humidity in a closed-circuit respiration chamber (Rogerson[3]). Urinary and fæcal nitrogen and carbon were determined.

The ratio of metabolizable to digested energy was slightly higher for the Ayrshires than for the Borans, due principally to a greater loss of urinary energy by the latter, but the ratio did not seem to be affected by water deprivation in either breed.

The change from 12 to 4 per cent crude protein ration with *ad lib.* water resulted in a decline of some 60 per cent in digestible energy intake and caused about a 20 per cent fall in the animals' heat production. The heat production of both Ayrshire steers and one of the zebus exceeded the metabolizable energy by 20–25 per cent. The heat production of the other zebu exceeded its metabolizable energy by 6 per cent. When fed the same 4 per cent crude protein diet but allowed water for only 30 min every 96 h, the heat production of the three steers previously in negative energy balance was reduced, while the other steer remained relatively unchanged. All four animals were then in approximate energy equilibrium.

Water balance data suggested that, although on 96-h water deprivation, the animals were not under severe stress. The average daily water intake over the period of three weeks on 96-h deprivation was 5·5 l.

Under the conditions of this experiment the results suggest that cattle on a low protein roughage diet might be better able to maintain themselves in positive energy balance if subjected to some degree of water restriction.

Propylene Phenoxetol as a Fish Anæsthetic

PROPYLENE phenoxetol has been found to be a suitable anæsthetic for fish at this laboratory. This substance has been used as a preserving agent by Owen and Steedman[1,2] and as a narcotic for relaxing animals prior to fixing for histological examination[3]. As an anæsthetic it has, like *M.S.222*, the advantage over urethane of not being a known carcinogenic substance. I have used it to quieten live fish when they are being weighed, and also as a narcotic to relax fish so that they may be fixed with the fin rays extended.

Two experiments with plaice, *Pleuronectes platessa* L., have been carried out which show the strength of the solutions to use under different conditions.

Small plaice of 16·5–20 cm were used at 6·5° C in 3 l. of solution each of 0·0025, 0·01, 0·025 and 0·05 per cent propylene phenoxetol. In the two weakest solutions the fish never became completely anaesthetized even after 6 h, though they were considerably quietened. In 0·01 per cent propylene phenoxetol the plaice were limp and did not curl when turned over after 30 min, and even after 6 h they recovered in 20–30 min when returned to clean sea-water. In the 0·025 per cent solution the plaice were again completely anaesthetized after 30 min, but they were not able to recover after 6 h in the solution. They took 30 min to recover their normal activity after 1 h exposure to the anaesthetic. In the strongest solution, 0·05 per cent, the fish were quite limp, and opercular movements had stopped after 30 min, but within 6 min of being transferred to clean water they were able to recover, and even after 1 h in the propylene phenoxetol recovery was possible. After 3 h in this solution the fish were dead.

The second experiment was carried out with larger fish of 27–33 cm in three strengths of propylene phenoxetol solution at 15° C. In the weakest solution, 0·005 per cent, the fish took 2 h to become completely anaesthetized and were unable to recover after 3 h in it. In 0·01 per cent propylene phenoxetol the plaice were limp after 20 min and could recover after 2 h in the solution, but not after 3 h. In the strongest solution, 0·025 per cent, the fish appeared completely anaesthetized after 5 min and were able to recover after 30 min in the propylene phenoxetol but not after 1 h.

From the experiments it is concluded that, for anaesthetizing fish for a period of more than 3 h, propylene phenoxetol must be used with great care since the strength of the solution and the temperature are critical. On the other hand, the experiments also show that it is a useful anaesthetic for periods of up to 1 h when a solution of 0·01–0·025 per cent can be used at normal laboratory and aquarium temperatures with fish of a wide range in size.

Tubularia crocea L. Agassiz in British Waters

RECENTLY some colonies of a tubularian hydroid were submitted to the British Museum (Natural History) by Dr. S. Markowski. The colonies were found attached to a rope at the intake of Cliff Quay Power Station, near Ipswich, on the River Orwell in July 1959. In general appearance the colonies resembled *T. larynx* in having a stem height of about 5 cm.

However, careful examination of the ripe female gonophores revealed that instead of the usual four, blunt, rounded tentacular rudiments, the gonophores possessed 6–8 laterally compressed ridges. The species was therefore something unusual for the British fauna and it was identified with *Tubularia crocea* L. Agassiz[1], a species of cosmopolitan distribution in warmer waters.

The latter species has previously been reported from British waters—by E. T. Browne[2], on the stern of a sailing ship in Plymouth Sound. This ship had arrived direct from Iquique, Peru, in September 1895, and it is evident that some colonies survived in Plymouth Sound for some years because two colonies were found in 1907. They were examined by Browne and are briefly recorded[3]. Browne's manuscript notes state that two specimens were found on the bottom of the laboratory boat on October 21, 1907; one of these polyps possessed the eight apical ridges on the female gonophores. Later (October 25), a special search of the buoys in the Sound yielded a large colony with gonophores containing actinulae. Browne noted that in the hydranth. the hypostome, stomach, collar and the spadix in the gonophores were a deep crimson. From a comparison of *T. crocea* and *T. larynx* side-by-side he noted that whereas the collar and neck of the hydranth were deeply pigmented in the species *crocea*, it did not, on the other hand, show any conspicuous coloration in that part in *T. larynx*. Other differences in trophosome indicated by Browne may be summarized as follows:

T. larynx	*T. crocea*
Expanded distal tentacles laterally compressed with sharp inner edge with inconspicuous narrow band of nematocysts.	Expanded distal tentacles with inner edge more rounded with broader nematocyst band.
Proximal tentacles with few scattered nematocysts.	Proximal tentacles thickly covered with nematocysts, more or less arranged in clusters.

A search of the British Museum collections did not reveal any genuine material of *T. crocea* from North American waters but a chance examination of the type material of *Tubularia polycarpa* Allman[4], from Coquimbo, Peru, yielded abundant fertile polyps. The gonophores of these, too, possessed the characteristic apical ridges in the female gonophores and in the male gonophores the tentacle rudiments were reduced to a slightly raised ring around the aperture: these characteristics indicate that this species must now be regarded as synonymous with *T. crocea*.

One other species, *Tubularia mesembryanthemum* Allman, remains to be considered. This was described and figured by Allman from the Gulf of Spezia at the same time that he described *T. polycarpa*. In his diagnosis of *T. mesembryanthemum*, Allman mentions that the female gonophore possesses "eight compressed, crest-like apical processes, which are replaced in the male by four small rounded tubercules". In the Ipswich material (but not Browne's Plymouth colonies) male gonophores have been seen. Agassiz declared that in his *T. crocea* there were no tubercules but whether *T. mesembryanthemum* is a distinct species on account of the four small rounded tubercules remains to be elucidated. The species which Bedot[5] recorded from Roscoff as having "les tubercules et les côtes longitudinales caractéristiques" thus retains the name *T. mesembryanthemum* unless the latter species proves to be identical with *T. crocea*.

It is significant that the occurrence of *Tubularia crocea* in a new British locality should be in the vicinity of a power station which uses sea water for cooling purposes.

Beginning of the Accumulation of Vanadium during the Early Development of the Ascidian *Phallusia mamillata* Cuvier

WHEN the uptake of vanadium by the tunicate *Phallusia mamillata* was investigated, it was observed[1] that small (young) animals (< 20 g fresh weight) accumulated the metal far more intensively than adult ones. This gave rise to the question at which stage of their development the animals become capable of absorbing vanadium. Furthermore, an attempt was made to find out whether this phase coincides with the differentiation of the blood cells, because in *Phallusia mamillata* the vanadium is present almost exclusively within specific blood cells, that is, vanadocytes.

Unfertilized and fertilized eggs (fertilization rate 80–90 per cent) were incubated in sea-water with an addition of nearly carrier-free vanadate-[^{48}V] at 18° C in the dark. The unfertilized eggs contained no more than 5 per cent of the total activity (10^6 c.p.m./ml. sea-water) even after an incubation period of 40 h. The activity of vanadium-48 is of the same order in all stages of development until the larva are about to hatch, that is, during 18 h (Fig. 1). Not until the appearance of swimming larva (up to 90 per cent of the fertilized eggs) does the accumulation of vanadium rise. During the following 18 h in single samples up to 80 per cent of the total activity offered was absorbed. At that time the absorption of the tail of the larva, which was now attaching itself to a substrate, had already begun. Further uptake of vanadium-48 was now reduced, obviously in consequence of the decreased concentration of vanadate in the medium.

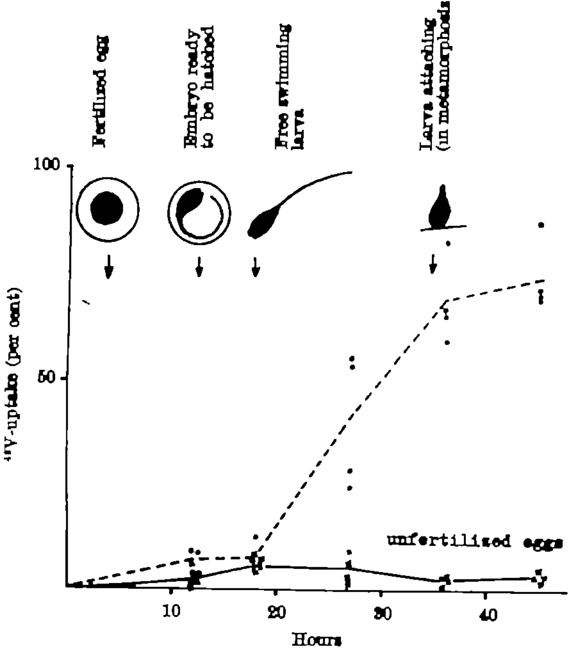

Fig. 1. The uptake of vanadate-[^{48}V] by *Phallusia mamillata* during development. ^{48}V-addition: 50 × 10^6 c.p.m./50 ml. sea-water containing an average of 8 × 10^4 fertilized resp. unfertilized eggs. Development at 18 ± 0·5° C in the dark during careful rocking (12 rocking movements/min). Four parallel samples; 5 ml. of each sample were withdrawn at the times indicated and the centrifuged material was washed three times with sea-water and measured by a scintillation counter

If it is assumed that the larva, the epidermis of which is already covered with a cuticle, absorbs the vanadium in the same way as the adult animals do[1], namely, through the branchial sac, it can be concluded that the gill slits develop during the larval stage[2], by which the branchial cavity may communicate via the atrial apertures with the outer medium. According to Kowalevsky[3] hæmatoblasts have separated at that time from the mesoderm and from the 'Darmdrüsenblattzellen' of the tail and migrated to the sides of the intestine, which now has opened into the cloaca.

Leeches as Endoparasites of Frogs

Leeches are adapted by their structure and physiology to an ectoparasitic, blood-sucking mode of life. Some have secondarily become predators, but none has obvious adaptations to endoparasitism. Those that enter the upper respiratory tracts of birds and mammals to suck blood from the mucous membrane usually remain only long enough to get their meal. It is therefore interesting to find that at least one species has been found living internally in frogs, usually in the lymph space beneath the skin but sometimes in the coelom. The leech is a species of *Philaemon*, possibly *P. grandidieri* Blanchard. The frogs are of six species and were taken in primary montane forest from the central mountains of the Australian Trusteeship Territory of New Guinea. They were at an altitude of 4,600–10,500 ft., between 143° and 146° E. on a latitude of approximately 6° S.

Rana grisea van Kampen (1 specimen infested) and *Hyla angularis* Loveridge (5 specimens) are ground-dwellers which rarely travel far from water. *Hyla becki* Loveridge (3 specimens) and *Hyla* n.sp. Tyler[1] (6 specimens) are normally found among low vegetation which they occasionally climb. *Nyctimystes kubori* Zweifel (1 specimen) and *N. narinosa* Zweifel (2 specimens) are typical tree-climbing frogs. Except for *Rana grisea* little is known of their breeding habits but it is unlikely that any exhibit arboreal spawning or direct development. They probably congregate at water for breeding and the leech may well attack them there. None of the frogs shows a scar marking the point of entry, so the leeches must have entered when they were very small and have lived and grown for a considerable period within the host. The jaws of the leech

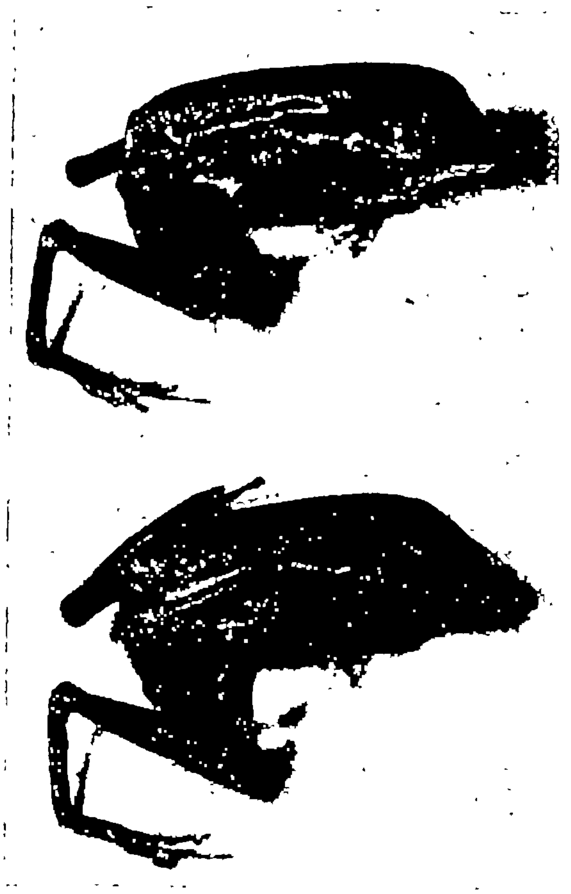

Fig. 1. Above, preserved specimen of *Hyla becki* showing the bulge in the dorsal surface caused by the leech in the subcutaneous lymph space. The split at the posterior end is a post-mortem effect. Below the same specimen with skin incised to show the leech in position. (*Photo* B. N. Donetil)

are well adapted to piercing skin; but it is surprising to find that almost one-third of the specimens had penetrated the muscles of the body-wall and settled in the coelom.

The leech shown in Fig. 1 is capable of taking almost the whole of the blood of the frog in one meal, and a prolonged endoparasitic relationship is possible only if the leech has modified its feeding habits to the extent of taking little and often. Those in the coelom would also have to adapt themselves to life in a very low oxygen concentration.

There is one previous record of such a phenomenon. Richardson[2] described the occurrence of *Batracobdella picta* (Verrill) in the dorsal subcutaneous lymph space of *Rana catesbiana* in Canada. In this case the entry seems to have been accidental and abnormal, for the leech is well known in the free-living state, and only two cases of the association were discovered from many hundreds of frogs examined. *Philaemon* is known as an ectoparasite in Madagascar, Australia, the Samoan Islands and Juan Fernandez[3], but we have discovered no records from New Guinea. Leeches are hermaphrodites and this might be regarded as an advantage in an endoparasite, but cross-fertilization is normal and the eggs are deposited in a cocoon. It therefore seems likely that either the leeches leave their hosts to breed or there is a breeding population of free-living leeches which has not yet been discovered. In either event this curious phenomenon throws interesting light on the origins of the endoparasitic habit.

Emerson Effect in Isolated Chloroplasts

The oxygen production resulting from flash illumination of chloroplast fragments was determined, using the method previously described[1]. Spinach leaves were ground in 0·35 M sodium chloride, 0·037 M magnesium chloride, 0·01 M ascorbate and 0·1 M *tris* buffer adjusted to *p*H 7·6. After centrifugation, the chloroplasts were washed once in the grinding medium but without ascorbate and broken in the same medium diluted ten times. The reaction mixture contained, in a final volume of 2 ml., chloroplast fragments containing 0·15 mg chlorophyll and the following (in μmoles): potassium ferricyanide, 3; sodium chloride, 70; magnesium chloride, 10; adenosine triphosphate, 1·5; inorganic phospate, 30; *tris* buffer, 50, adjusted to *p*H 7·4. Throughout the measurements the reaction mixture was maintained at 5° ± 1° C and was flushed with nitrogen gas containing less than 1 p.p.m. oxygen. Flashes, from Philips photoflux bulbs, were of sufficient intensity to saturate the reaction ($2·8 \times 10^{-4}$ lumens, 35-msec duration). The change of oxygen yield per single flash was used to determine the rate of decline of activity of the chloroplasts with time.

It has been shown previously[1], with white light, that the yield of oxygen from a single flash is greatly increased when an algal suspension is illuminated with very low intensity continuous light. These experiments have been repeated using isolated chloroplasts with monochromatic flash and background illumination. The flash was filtered through a GAB filtra flux interference filter with transmission either at 644 ± 13 mμ or 697 ± 7 mμ. The continuous light was passed through a *D*.290 Hilger and Watt's small grating monochromator, with the slit width adjusted to give a band-width not greater than 5 mμ. The intensity was approximately the same at all wave-lengths. The chloroplasts were illuminated with continuous monochromatic light of a selected wave band until a steady rate of photosynthesis was obtained; then the additional oxygen produced by a single flash was measured. The yield of oxygen from the flash as a percentage of the yield obtained in darkness without any continuous illumination is plotted against the wave-length of the continuous light and is shown in Fig. 1. With a flash at 697 mμ, the greatest yield of oxygen was obtained when the continuous light was at 651 or 675 mμ, with a maximum effect at 675 mμ. With a flash at 644 mμ, the greatest yield was obtained when the continuous light was at 675 or 700 mμ. The wave-length for the maximum enhancement of the yield from the flash was unchanged when the intensity of the continuous light was varied several fold

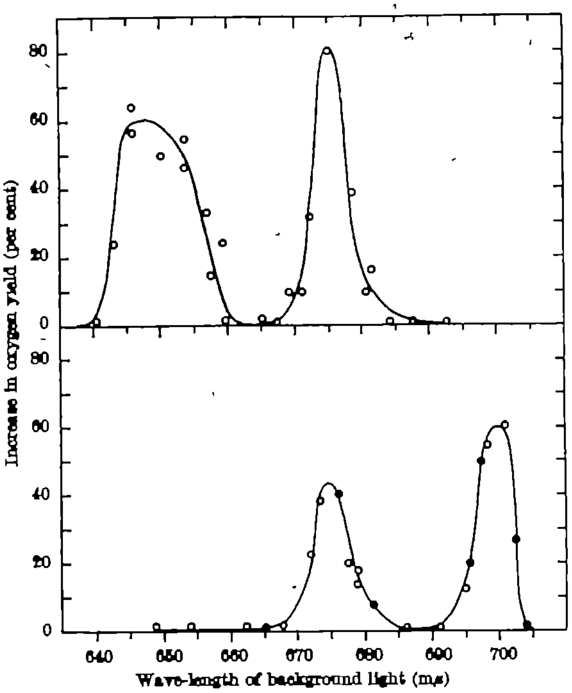

Fig. 1. Percentage increase in yield for a monochromatic flash at 697 (upper) or 644 (lower) as a function of the wave-length of the continuous monochromatic illumination. The percentage is expressed as the increase in yield compared with a flash given in darkness

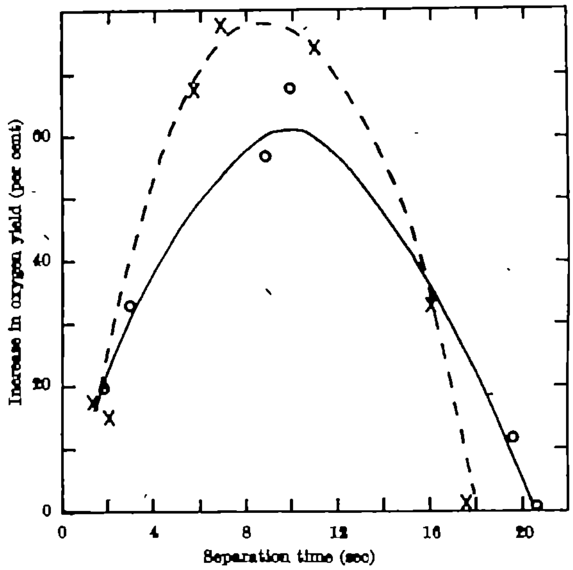

Fig. 2. Yield per flash as a function of the time-intervals between the cessation of illumination and the flash. ——, Yield from a flash of 697 mμ following illumination at 656 mμ; – – –, yield from a 644-mμ flash following illumination at 700 mμ

The marked dependence of oxygen yield on wave-length indicates the existence of different chlorophyll forms which must have sharp absorption bands.

In other experiments the chloroplasts were illuminated by a single flash given at a measured time-interval after the continuous background light was turned off. Fig. 2 shows the yield of oxygen from the flash as function of the time between the cessation of the background illumination and the flash. Even 8 sec after the continuous light was turned off, the yield of oxygen from the flash was increased compared with that from the same flash given after a prolonged dark period. The results were appreciably the same whether the flash was at 697 mμ and the background light at 651 mμ, or the flash at 644 mμ and the background at 700 mμ.

These results show that isolated chloroplasts reducing ferricyanide exhibit the same type of enhancement effect as has previously been observed with photosynthetic plants[2], and with *Chlorella* reducing quinone[3]. Furthermore, they demonstrate in spinach leaves, chlorophyll forms which absorb at essentially the same wave-lengths as those observed by French and Fork[4], in leaves of different plants and in green algae, using the differential spectrophotometer. If two pigment systems are postulated (one absorbing at 675 and 700 mμ and the other at 651 and 675 mμ in spinach) catalysing two separate photochemical reactions the products of which interact in photosynthesis, a lifetime for the products of several seconds is indicated. Our observations were at 5° ± 1° C, whereas those of French were at room temperature. French found no enhancement, in *Chlorella*, of the yield at 670 mμ as a result of simultaneous illumination with 650 mμ. When studying the reactions of isolated chloroplasts the effect of a light-induced respiration, if present at all, may be smaller than with whole cells. It is not clear as yet whether this apparent difference in wave-lengths is due to the difference in temperature or to the complications introduced in a respiring system. Witt[5] has observed absorption changes consequent on illumination and suggested that the longest lifetime of any intermediate in photosynthesis is of the order of 10^{-2} sec. Our work suggests the existence of a long-lived intermediate which may not be detectable by the method of difference spectroscopy used by Witt, but which is required in the reactions leading to the production of oxygen.

We are grateful to the Royal Society for a Government grant-in-aid of this investigation. One of us (P. M. B.) holds a postgraduate studentship of the University of London. We are also grateful for a grant from the Central Research Fund of the University of London.

ENTOMOLOGY

Insecticide absorbed by the Central Nervous System of Susceptible and Resistant Cockroaches exposed to Dieldrin

PENETRATION and metabolism studies carried out in this Department on susceptible and resistant houseflies, using the sulphur analogue of dieldrin or a non-insecticidal bromine derivative of aldrin[1]; aldrin, dieldrin, isodrin or endrin[2]; failed to reveal any differences between the strains which would explain the mechanism of resistance. There is some evidence that dieldrin acts on the central nervous system of susceptible insects[3] and it seemed possible that dieldrin failed to reach the sensitive cells of this system in the resistant insect due to some internal local barrier, for example, a dieldrin impermeable neural lamella.

In order to investigate this, dieldrin resistant and susceptible *Blattella germanica* were treated topically with dieldrin (10 μg in 2 μl. acetone) on the dorsal abdomen and kept at 25°. The susceptible insects became prostrate within about 6 h of treatment; but the resistant ones were unaffected. The intact cockroaches were rinsed externally in acetone/petroleum ether (20 : 80 by vol.) to remove unabsorbed insecticide and the nerve cords dissected out. The nerve cords were homogenized with acetone–petroleum ether and the dieldrin in the extract

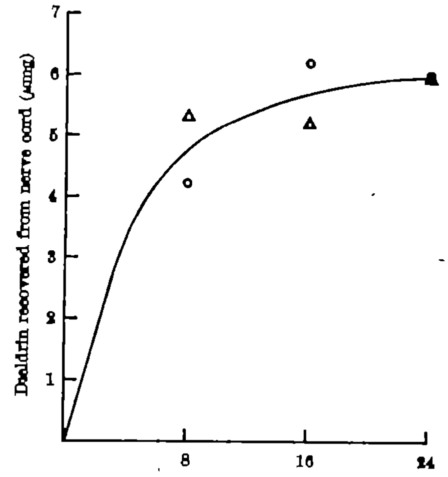

Fig. 1. Dieldrin uptake by susceptible and resistant *Blattella germanica*. ○, Dieldrin found in susceptible nerve cord, △ dieldrin found in resistant nerve cord

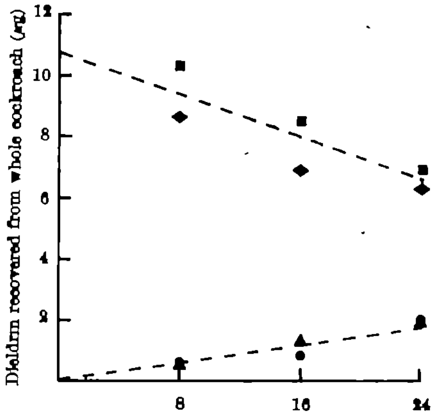

Fig. 2. Dieldrin uptake by susceptible and resistant *Blattella germanica*. ■, Dieldrin found on outside of resistant insect; ◆, dieldrin found on outside of susceptible insect; ●, dieldrin found in tissues of susceptible insect; ▲, dieldrin found in tissues of resistant insect

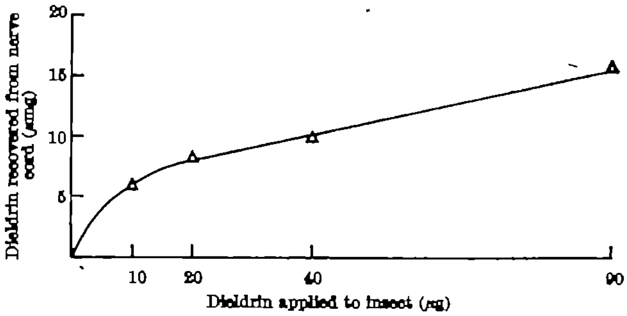

Fig. 3. Dieldrin uptake by resistant *Blattella germanica*. △, Dieldrin in nerve cord of resistant insect

assayed by gas-liquid chromatography. The results are shown graphically in Fig. 1. Increasing doses of dieldrin were topically applied to the resistant strain and the animals left for 24 h before the insecticide in the nerve cord was assayed (Fig. 3). None of these insects was showing any signs of poisoning. Penetration into the whole insect was studied in both strains, Fig. 2.

From Figs. 1 and 2 it will be seen that there were no differences between the amounts of unchanged dieldrin recoverable from the tissues either of the whole animal or the nerve cord in the resistant or susceptible cockroach.

Fig. 3 shows that in the resistant animal the concentration of dieldrin in the nerve cord increased with increased topical application of insecticide.

These results are not consistent with the existence of a dieldrin-impermeable membrane around the nerve cord of the resistant animal.

These and earlier investigations therefore suggest that resistance is not due to metabolism or to lack of penetration of the insecticide, but rather to the ability of the resistant insect to withstand higher concentrations of unchanged dieldrin within the central nervous system itself without showing any signs of poisoning.

This work was supported in part by a research grant from the World Health Organization.

Differential Growth Response of the Male and Female Rice Moth to Antibiotic Supplements

During the course of the nutritional studies[1] on the rice moth, *Corcyra cephalonica* Staint., to determine the comparative value of several commercially available antibiotic feed supplements, it was observed that in some cases male moths of *Corcyra cephalonica* Staint. exhibited a higher growth response than the females receiving dietary antibiotics in their larval stages. A survey of the literature failed to disclose specific observations on this phenomenon among insects, although Palafox and Rosenberg[2] observed that male chicks respond in a more satisfactory manner to antibiotic feed supplements than the female.

The culture of *Corcyra* was maintained as described earlier[3]. For experimental purposes 10 in. × 2 in. glass vials were filled with 120 g of crushed 'juar' (*Sorghum vulgare*). Weighed quantities of the antibiotics penicillin, oleandomycin and terramycin were mixed in the diet at the rate of 100 p.p.m. by thoroughly distributing the premix in the vials, containing the food. Premix was prepared in glucose in convenient amounts for efficient mixing. The control groups received an equal amount of glucose only in the diet. Fifty freshly laid eggs (24-h layings) were introduced in the experimental vials containing different antibiotic-feed supplements. Six replications were used for each treatment. Moths emerging from the different treatments, after completing their development in the different antibiotic-feed supplements, were sorted out for males and females. Ten males and an equal number of females were weighed individually from each replication to assess the growth response in the sexes. Results are summarized in Table 1. The growth indexes shown in Table 1 were obtained by dividing the average body-weights of either males or females in each experimental group by the mean body-weight of the respective control group.

Table 1. Comparative Growth Indexes of Male and Female as Influenced by Antibiotic Feed Supplements

Supplement	Growth Indexes (%) Male	Growth Indexes (%) Female
Penicillin	112·2	106·4
Oleandomycin	99·5	100·7
Terramycin	108·3	103·2
Control	100·00	100·00

From these results it is seen that the males fed on penicillin-feed supplements grew 12·2 per cent heavier than their controls, and those fed terramycin grew 8·3 per cent heavier, whereas the females grew only 6·4 per cent and 3·2 per cent heavier than their respective controls. On analysis, F value between sex growth indexes was highly significant ($P < 0.01$). Oleandomycin proved ineffective in enhancing the growth of either male or female.

I thank Mr. B. N. Jha, vice-chancellor, for encouragement, and Dr. B. K. Srivastava, entomologist to the Government of Rajasthan, Jobner, for guidance. I also thank M/S. Dumex Private, Ltd., Bombay, for gifts of the antibiotics.

A Modified Window-trap for Assessment of Fumigant Insecticides in Experimental Trap-huts

We are assessing the toxicities of new insecticidal compounds as part of a World Health Organization programme to evaluate possible substitutes for the chlorinated hydrocarbons to which anopheline mosquitoes in many countries have become resistant. The experimental trap-hut of the Muirhead-Thomson type[1] is used for this assessment as it is a research tool of proved value. There are, nevertheless, a number of weaknesses in its design that lead to errors in assessing insecticide-toxicity:

(1) Nearly all resting is on the roof so that the toxicity of the roof-substrate has an over-riding effect on overall mortality.

(2) In the presence of a fumigant insecticide an unassessed proportion of mosquitoes die simply due to confinement in the atmosphere of the insecticide in the window-trap, whereas under natural conditions they would have escaped from the hut and survived.

(3) An unassessed proportion of hut-entering mosquitoes leave through the eaves.

Investigations of these three points are in progress in our outstations at Magugu in Tanganyika, and at Taveta in Kenya. Errors due to the first point have been largely overcome by assessing mortalities in huts with different types of roof-surfaces[2]. Errors due to the second point have been greatly reduced by a simple technique which is the subject of this communication. The third point is still unresolved, but is receiving attention.

Table 1. Mortality of Blood-Fed Mosquitoes in Window-Traps (W.T.) with Funnels of Cotton Mosquito Netting and of Sheet Polythene

Age of dispenser (days)	Exposure period (h)	Species of mosquito	Percentage mortality with number studied in parentheses: W.T. with netting funnel	Percentage mortality with number studied in parentheses: W.T. with polythene funnel

28	4	,,	76 (39)	0 (36)
32	4		0 (42)	2 (40)

[illegible]

The normal type of window-trap, fitted to an experimental hut, is supported on a frame that fits into a window 1 ft. square. There is an exit funnel of cotton mosquito netting, with a mouth 1 in. in diameter, and a trap of similar netting which has sides and a back 1 ft. square. Thus in a hut with a fumigant insecticide such as 'Dichlorvos' there is a diffusion of vapour from the hut into the window-trap through an aperture virtually 1 ft. square since the vapour diffuses readily through the mosquito netting. By changing the funnels of netting for ones of polythene sheet (250 gauge) the area for diffusion of 'Dichlorvos' vapour was reduced from approximately 1 ft.^{2} to 1 in.^{2}, while the exit aperture for mosquitoes remained the same size. The results in Table 1 show that this modification greatly reduced the mortality of blood-fed mosquitoes confined in the window-traps. The percentage mortalities are for 24 h after exposure and are corrected against control mortalities by Abbott's formula[3]. Complementary chemical determinations, using a method to be published later, showed that the concentration of 'Dichlorvos' in the window-traps with plastic funnels was of the order of 0·005 μg/l., compared with 0·020 μg/l. in traps with netting funnels.

The modified window-trap has now been incorporated into our routine trials with experimental huts to assess the toxicity of 'Dichlorvos' to naturally entering mosquitoes.

MICROBIOLOGY

Deoxyribonucleic Acid Type attributable to a Bacterial Endosymbiote in the Protozoon *Crithidia (Strigomonas) oncopelti*

In the course of an investigation of the occurrence of two paths of lysine biosynthesis[1,2], tracer and enzyme experiments provided evidence that the trypanosomatid flagellate, *Crithidia* (*Strigomonas*, *Herpetomonas*) *oncopelti*, contains a bacterial endosymbiote[3,4]. This evidence was supported by electron microscopy: the inferred endosymbiote shows structures consistent with a cytoplasmic membrane, a cell wall, and nuclear zones, and endosymbiotes which are dividing, as judged by the presence of a constriction, exhibit membrane septa[4,5]. The protozoon can be 'cured' of its endosymbiote with penicillin[4,5]. It was suggested that the endosymbiote furnishes lysine and probably other metabolites to the protozoon, which in turn provides a protective environment for the endosymbiote[3,4]. This suggestion took into account: (*a*) the exceptionally simple nutritional requirements of the protozoon, which were recorded by Newton[6]; (*b*) the presence of 'bipolar bodies' within the protozoon, which were described by Newton and Horne[7] and afterwards recognized as the endosymbiote[3,4]. Attempts to demonstrate deoxyribonucleic acid (DNA) in the bipolar bodies had given inconclusive results[7].

In parallel experiments, DNA samples from *C. oncopelti* and other protozoa were examined for their base composition by their buoyant density in a caesium chloride gradient[8,9]. The buoyant density is known to be linearly related to the mole per cent guanine plus cytosine (G + C) composition of DNA, and may correlate with the taxonomic position of the organism involved[10]. For *C. oncopelti*, three DNA bands were observed in the caesium chloride gradient (Fig. 1): a quantitatively major one, corresponding to a density of 1·709 g/c.c. and presumably derived from the protozoan nucleus, and two minor ones with densities of 1·699 g/c.c. and 1·691 g/c.c. The base compositions corresponding to these densities are 50, 40 and 32 per cent G + C, respectively. Accordingly, it was of interest to examine the possibility that one of the minor bands represents DNA from the endosymbiote.

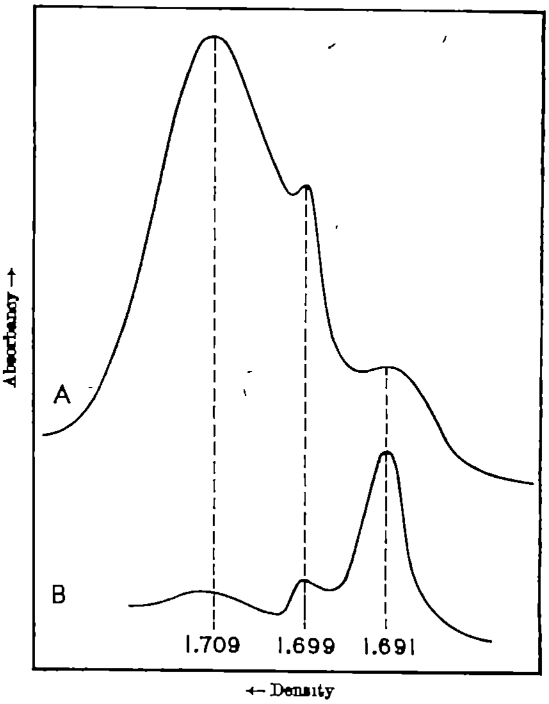

Fig. 1. Banding patterns of DNA from cells of endosymbiote-containing *C. oncopelti* (*A*) and from isolated cells of the endosymbiote (*B*)

Preparations of the endosymbiote were obtained as follows. Cells of *C. oncopelti* were collected during active growth on peptone–liver extract–glucose medium and were suspended in 0·2 M (potassium) phosphate buffer at *p*H 7·0, made 0·25 M in sucrose. The suspension was treated with glass beads in a Mickle disintegrator until approximately 80 per cent of the protozoan cells were disrupted, and was then fractionated by centrifugation; the material sedimenting (for 10 min) between 900 and 1,200*g* was collected. Microscopic examination indicated that this fraction consisted largely of the endosymbiote, along with some fine debris. This fraction was suspended in 0·2 M phosphate at *p*H 7·0, containing 0·25 M sucrose and 0·01 M magnesium sulphate, and was treated with deoxyribonuclease to destroy, so far as possible, any contaminating protozoan DNA. The treated suspension was made 0·04 M in trisodium citrate, and was centrifuged. The sedimented material was washed by centrifugation with a solution containing 0·15 M sodium chloride, 0·25 M sucrose, and 0·015 M trisodium citrate, and was then suspended in a solution containing 0·15 M sodium chloride and 0·015 M trisodium citrate. The resulting suspension was lysed by addition of 20 per cent sodium lauryl sulphate (0·5 part by volume per part of suspension), and was heated at 55° C for 10 min. The lysed suspension was subjected to the procedure for the extraction of DNA, essentially as previously described[11].

The banding patterns of the DNA obtained from the endosymbiote-containing protozoa (Fig. 1*A*) and from the isolated endosymbiotes (Fig. 1*B*) indicate that the minor band of density 1·691 g/c.c. of tracing *A* and the major band of tracing *B* represent DNA from the endosymbiote. The calculated base composition (32 per cent G + C) for the DNA from the endosymbiote resembles that for the DNA from various bacteria, pleuropneumonia-like organisms, and kappa[8,10,11]. The origin of the bands of density 1·699 g/c.c., representing minor components in tracings *A* and *B*, remains unknown. The narrow width of these bands, which may reflect a high degree of homogeneity or high molecular weight or both, suggests that these bands may correspond to DNA from specialized homogeneous structures or a virus. If so, the cæsium chloride density gradient technique would be useful in investigating not only bacterial endosymbiotes, but also other inclusions exhibiting genetic continuity within a cell.

This work was aided by grants from the National Science Foundation and the U.S. Public Health Service, and by a contract between the Office of Naval Research, Department of the Navy, and Rutgers, The State University. The strain of *C. oncopelti* used was kindly furnished by Dr. F. G. Wallace.

VIROLOGY

Lettuce Necrotic Yellows Virus

A DESTRUCTIVE virus disease of lettuce, causing extensive crop losses sometimes as high as 100 per cent. was recognized in Victoria in 1954 as being distinct from the lettuce mosaic disease. Until 1959, however, all attempts to transmit the virus to lettuce with aphids which commonly infest lettuce, with thrips, leaf-hoppers and sap inoculation methods were unsuccessful. In that year a virus was transmitted mechanically to *Nicotiana glutinosa* L. from many diseased lettuce plants and from apparently normal common sowthistle (*Sonchus oleraceus* L.) plants. These isolates were, at first, incorrectly identified as mild variants of the tomato spotted wilt virus[1], because of the remarkable similarity between the diseases caused by the two viruses on some common hosts, including lettuce. The tomato spotted wilt virus has been isolated occasionally from lettuce; but it is of minor significance in Victoria, Australia, possibly because common strains found here on tomato and other hosts do not appear to infect lettuce in Nature.

The causal virus, which appears to be distinct from any previously described, is to be named lettuce necrotic yellows virus. The virus is unique in its host and vector relationships. It is not seed-borne in lettuce, or any other host so far examined, but it is widely distributed in Nature on *S. oleraceus*, which is its only known source. It is transmitted specifically, and most efficiently after moulting, by the aphid *Hyperomyzus lactucae* L., which breeds only on *Sonchus* spp. although currants (*Ribes* spp.) are reported[2] to be an overwintering host, and may be the original source of the virus. This possibility is being investigated. The aphid transports the virus to lettuce on which it feeds transiently, but not preferentially. It dies without multiplying when caged on lettuce for several days.

In addition to the hosts already mentioned, the virus has been experimentally transmitted to and recovered from *Datura stramonium* L., *Gomphrena globosa* L., petunia, tomato and spinach. Attempts to infect *Nicotiana tabacum* L. var. *xanthi* and Turkish have not been successful. Lettuce is extremely difficult to infect by sap inoculation, and mechanical transmission of the virus from lettuce to lettuce has not been achieved.

Sowthistle, lettuce and *Lactuca serriola* L. are the only hosts from which the virus has been recovered in Nature.

Thermal inactivation of the virus in expressed sap from *N. glutinosa* occurred between 52°–54° C after 10-min exposure. Its longevity *in vitro* ranged from 2 to 8 h for individual isolates. These differences may be due to different concentrations of the virus rather than to strain differences.

There is evidence that the lettuce necrotic yellows disease can be effectively controlled by eradicating sowthistles in the close vicinity of lettuce crops.

GENETICS

A New Chromosome Number and Karyotype in *L. radiata*

CYTOLOGICAL investigations in several species of *Lycoris* have been carried out by a number of workers[1-4]. The somatic chromosomes here are fairly large in size and few in number, reported to be between 12 and 33. Of these 12, 13, 14, 15, 17, 22, 29 + 1 *B*, 30 and 33 have already been counted. In karyotype analysis the chromosomes could be classified broadly into *V* and rod-shaped types No species have been found with all *V* chromosomes in their complement but those with 22 and 33 chromosomes have been observed to have rod chromosomes with subterminal constrictions only (*L. haywardii*, *L. radiata*, *L. sanguinea* and *L. sprengeri*). Among those with both *V* and rod chromosomes in their complement some have rods of the nearly terminal constrictions only (*L. aurea*, *L. chinensis*, *L.* '*sperryi*' and *L. traubii*), others have rods with subterminal constrictions (*L. albiflora* and *L. elsiae*), still others have rods with subterminal and nearly terminal constrictions (*L. caldwellii*, *L. squamigra*, *L. incarnata* and *L. houdyshelii*). In *L. chinensis* one *V* chromosome was observed to be much shorter in size (designated small *v*) than the rest of *V* chromosomes[4].

In *L. radiata* somatic chromosome numbers have been reported with 22 and 33 chromosomes and the usual karyotype consists of only rod chromosomes with subterminal constrictions (Fig. 1*A*). Recently, while making cytological observations on a number of bulbs labelled as *L. radiata*, one was found to have a chromosome number and karyotype quite different from the others. Here 31 rod chromosomes (all with subterminal constrictions), 1 *V* chromosome and 1 small chromosome with nearly median constriction were observed (Fig. 1*B*). Hence, $2n$ number here could be counted as 32 + 1 *B* or supernumerary chromosome. This small chromosome was much shorter in size in comparison with the rest of the chromosomes. Previously only one species of *Lycoris* has been found with a *B* or supernumerary chromosome, that is, in *L. incarnata* with 29 + 1 *B* (ref. 5). In all the other bulbs 33 rod chromosomes were observed with subterminal constrictions (Fig. 1*A*). All these bulbs with 33 rod chromosomes and that

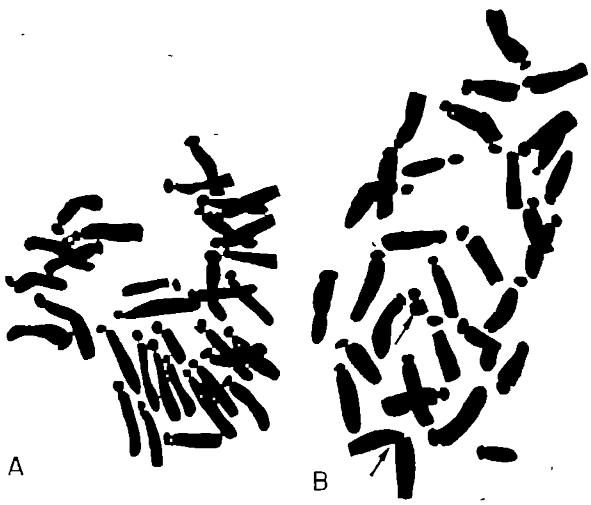

Fig. 1. *A*, *Lycoris radiata*, somatic metaphase with 33 rod-shaped chromosomes (× *c*. 1,100); *B*, *L. radiata*, somatic metaphase with 31 rod-shaped, 1 *V*-shaped and 1 *B* or supernumerary chromosome. *V* and *B* or supernumerary chromosome shown by arrows (× *c*. 1,100)

with 31 *R* + 1 *V* + 1 *B* chromosome had leaves like those in *L. radiata* but none of these has flowered yet.

With regard to the finding of a *V* chromosome in *L. radiata* the mechanism of the formation of a *V* chromosome from two rods with subterminal constrictions through reciprocal translocation or fusion can be taken into account. The formation of a *V* chromosome by these methods has been suggested by Cave and Bradley[9] in *Miersia chilensis*. Although the exact nature of the origin of a *B* or supernumerary chromosome is not known, Darlington's[10] idea regarding the origin of this type of chromosome from an *A* seems relevant.

This new chromosome number and altered karyotype observed in *L. radiata* once more shows the rôle of structural change in speciation and in the formation of chromosome races in *Lycoris* (Table 1).

Table 1. Chromosome Number and Karyotype in *Lycoris*

Lycoris taxa	Types of chromosomes *V*	*R*		Chromosome No.	Possible potentialities in rod chromosomes
aurea	10	2		12	22 *R*
	9	4		13	22 *R*
	6	8		14	22 *R*
	7	8		15	22 *R*
'sperryi'	7	8		15	22 *R*
traubii	10	2		12	22 *R*
	9	4		13	22 *R*
chinensis	7	9		16	22 *R*

MISCELLANEOUS

Storage of Standardized Radioactive Solutions

There is considerable interest in the storage of radionuclide solutions in polythene bottles. Keith, in a recent communication[1], indicated the losses of solvent through the walls of polythene ampoules. The experience of our laboratory is comparable in this respect, but it might be noted that the rate of loss was extremely high from concentrated hydrochloric acid solutions where apparently gaseous hydrochloric acid was being transferred through the walls. We believe that the following information on other types of losses will be of interest.

The stability of nuclide solutions in polythene bottles and possible losses through adsorption on the walls have been questioned many times. A series of tests was performed to determine if appreciable losses occurred in the normal use of these bottles for solution storage and handling. The results obtained should be considered only as a guide and appropriate tests carried out as needed.

Six nuclides (cæsium-137, cerium-144, zirconium-95, iodine-131, ruthenium-106 and barium-140) were obtained from Oak Ridge, aliquots taken, diluted and stored in sealed polythene ampoules (6 ml. capacity) for a period of from 10–63 days.

Nuclide	Carrier	Acid	Percentage retained after rinse Water	Acid

	–	×	0	

* With either zirconium or niobium or with both as carriers.

In each case, duplicate samples were prepared in water, with carrier (1 mg/ml.) and with 0·1 N hydrochloric acid solution, except in the case of iodine-131 where sodium sulphite (*p*H at 8) was used, and zirconium-95 where oxalic acid was used.

The samples were γ-counted in a 3·25 in. × 5 in. sodium iodide well-crystal, with a 1 in. × 1·75 in. well surrounded by a stainless steel, mercury-filled shield. All samples were counted for 5 min and a counting error of at least 1 per cent was maintained. The average counter background was 225 c.p.m. After the initial count, the drawn stems of the ampoules were cut off, the bottles rinsed four times with warm water, and re-counted. In the case of residual activity, the bottles were re-washed four times in a 1 N hydrochloric acid solution and re-counted.

The results are shown in Table 1. In every case except one, the nuclide may be kept in solution by addition of appropriate acid or carrier. Ruthenium adsorbs appreciably on polyethylene and even at best 25 per cent will remain on the walls.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, March 25

Royal Society of Medicine, Library (Scientific Research) Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Mr. H. Palmer: “The Pharmaceutical Industry—What it is and What it Does”.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. John D. Woods and Mr. Brian B. Matthews: “Archaeology Under the Sea”.

Monday, March 25—Wednesday, March 27

Institution of Electrical Engineers, Electronics Division (at Savoy Place, London, W.C.2)—Convention on “H.F. Communication”.

Tuesday, March 26

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. D. C. Pepper: “Polymerization of Styrene by Strong Acids”.

Society of Instrument Technology, Measurement Technology Section (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. L. Finkelstein: “Principles of Measurement”.

Tuesday, March 26—Thursday, March 28

Institute of Metals (at Church House, Great Smith Street, London, S.W.1)—Spring Meeting.

Royal Institution of Naval Architects (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, S.W.1)—Spring Meeting.

Tuesday, March 26—Friday, March 29

Effluent and Water Treatment Exhibition and Convention (at Seymour Hall, Seymour Place, London, W.1).

Wednesday, March 27

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Dr. J. Smagorinsky: “The General Circulation” (Symons Memorial Lecture).

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Mr. J. I. Krzymuski: “Economics of Air Cooling in a Refinery”.*

Royal Institute of Chemistry, London Section (in the Lecture Theatre, Science Museum, South Kensington, London, S.W.7), at 5.30 p.m.—Discussion Meeting on “Education and Training in Chemistry”.

British Institution of Radio Engineers (Joint meeting with the Institution of Electrical Engineers, at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. R. L. Gregory: “Instruments in Experimental Psychology”.

Society of Chemical Industry, Food Group (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. D. H. Ward: “Thinking Statistically in the Food Industry”.

Wednesday, March 27—Saturday, March 30

Society of Environmental Engineers (at the Mechanical Engineering Department, Imperial College of Science and Technology, Exhibition Road, London, S.W.7)—Symposium and Exhibition—“Environmental Testing: The Key to Reliability in Industry”.

Thursday, March 28

Institution of Mechanical Engineers, Applied Mechanics and Lubrication and Wear Groups (at 1 Birdcage Walk, Westminster, London, S.W.1)—All day Symposium on “Fatigue in Rolling Contact”.

Plastics Institute (at the Wellcome Building, Euston Road, London, N.W.1), at 4 p.m.—Symposium on “Reinforcements other than Glass Fibres”.

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. A. Charlesby and Mr. P. G. Garratt: “Radiation Protection in Irradiated Dimethylsiloxane Polymers”; Mr. A. Charlesby and Mr. J. Morris: “Enhanced Ionic Polymerization of Styrene Induced by Radiation”.

Institution of Mechanical Engineers, Industrial Administration and Engineering Production Group (at the College of Science and Technology, Manchester), at 6.45 p.m.—Mr. L. A. Williams and Mr. R. J. Finlayson: “Engineering Market Research Theory and Practice”.

Institution of Mechanical Engineers, Hydraulic Plant and Machinery Group (at the College of Further Education, Harlow), at 7.30 p.m.—Mr. R. C. Worster: The Effect of Volute Shape on Centrifugal Pump Performance”.

Thursday, March 28—Friday, March 29

Biochemical Society (in the Department of Biochemistry, University College, Gower Street, London, W.C.1), at 4.30 p.m. on Thursday—Annual General Business Meeting; 10 a.m. on Friday—Original Communications.

Friday, March 29

Royal Society of Medicine (at 1 Wimpole Street, London, W.1), at 10 a.m.—All-day Symposium on “Chemotherapy of Cancer”.

British Mycological Society, Plant Pathology Committee (in the Large Physics Lecture Theatre, Imperial College of Science and Technology, London, S.W.7), at 10.45 a.m.—Symposium on “Experimental Techniques and Methods in Plant Pathology”.

Society of Environmental Engineers (at Imperial College, London, S.W.7), at 2.30 p.m.—Annual General Meeting.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. L. S. Penrose, F.R.S.: “Limitations of Eugenics”* (The Woodhull Lecture).

Monday, April 1

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.30 p.m. Mr. Norris D. McWhirter: “Facts and How to Find Them”.

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on “Passenger Handling Within Large Buildings”.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—“Tribes of the Xingu”—Films with commentary by Mr. Adrian Cowell.

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. H. Coates: “Modern Aspects of Phosphorus Compounds”.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (preferably with a knowledge of isotope techniques and enzyme studies) in the Department of Biochemistry, for duties involving teaching at postgraduate level and research—The Secretary, Institute of Psychiatry (University of London), The Maudsley Hospital, Denmark Hill, London, S.E.5 (March 27).

Lecturer (with a good honours degree or equivalent qualification in mathematics or statistics and postgraduate research or industrial experience) in the Department of Mathematics—The Secretary, Welsh College of Advanced Technology, Cathays Park, Cardiff (March 30).

Lecturers or Assistant Lecturers (two or three posts) in the Department of Zoology—The Registrar, The University, Bristol (March 30).

Reader in Polymer Chemistry or Technology—The Secretary, Welsh College of Advanced Technology, Cathays Park, Cardiff (March 30).

Technician in the Department of Genetics, for work concerned with the culture of micro-organisms—The Registrar, The University, Liverpool 3, quoting Ref. No. CV/277/N (March 30).

Assistant Lecturer (with special interests in petrology and mineralogy) in Geology—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 5).

Biochemist in the Endocrine Unit—The Registrar, The University, Liverpool, quoting Ref. No. CV/276/N (April 6).

Lecturer in the Department of Electric Power Engineering—The Registrar, The University, Liverpool, quoting Ref. No. CV/278/N (April 6).

Junior Lecturer (preferably with a registrable medical qualification and an interest in histology) in Physiology—The Registrar, Trinity College, Dublin 2, Republic of Ireland (April 8).

Assistant Lecturer in Botany or Zoology—The Secretary to the Trustees, Magee University College, Londonderry, Northern Ireland (April 10).

Second Chair of Applied Mathematics in the Newcastle Division of the University of Durham—The Secretary to Senate, University Office, 1A Kensington Terrace, Newcastle-upon-Tyne 2 (April 10).

Demonstrator in Pharmacology—Dr. T. D. Kellaway, Secretary of the Appointments Committee, Department of Pathology, The University Tennis Court Road, Cambridge (April 11).

Lecturer in Botany at the Royal College, Nairobi, to teach angiosperm taxonomy and plant ecology to London B.Sc. (General Honours) level and help with other courses in the Department—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 12).

Lecturer (with an appropriate degree in applied science in industrial chemistry or chemical engineering) in Industrial Chemistry at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Brisbane and London, April 12).

University Nuclear Physics Research Fellows (Ph.D. standard, with special aptitude for research in high or low energy nuclear physics)—The Registrar, The University, Liverpool, quoting Ref. No. CV/279/N (April 13).

Junior Lecturer in Botany—The Registrar, Trinity College, Dublin 2, Republic of Ireland (April 15).

Senior Lecturer or Lecturer in Mechanical Engineering at the University of Natal, South Africa—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, April 15).

Senior Lecturer or Lecturer in Pathology in the Faculty of Medicine at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 15).

Senior Lecturer or Lecturer in Veterinary Preventive Medicine and Veterinary Public Health in the Faculty of Veterinary Science of the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 15).

Chair of Theoretical Physics tenable in the Durham Division of the University—The Registrar and Secretary, Durham Colleges, 38 North Bailey, Durham (April 17).

Reader in Geophysics in the Durham Division of the University—The Registrar and Secretary, Durham Colleges, 38 North Bailey, Durham (April 17).

Second Chair of Geography tenable in the Durham Division of the University—The Registrar and Secretary, Durham Colleges, 38 North Bailey, Durham (April 17).

Experimental Officer (with a degree in physics or in textiles and preferably some postgraduate experience assisting in knitting research) in the Division of Textile Physics, Commonwealth Scientific and Industrial Research Organization, Ryde, Sydney, Australia, to assist in a study of dimensional stability and mechanical properties of cloth knitted in a variety of ways—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 465/177 (April 20).

Research Officer (with at least a university honours degree in science, or equivalent qualifications, together with some years of appropriate postgraduate research experience, and preferably experience in reaction kinetics surface or solid-state chemistry, and/or vacuum techniques) IN THE DIVISION OF COAL RESEARCH, Commonwealth Scientific and Industrial Research Organization, North Ryde, N.S.W., Australia, to undertake fundamental research on the mechanism of catalysis of the reactions of carbon with oxidizing gases—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 480/428 (April 20).

LECTURERS IN MECHANICAL ENGINEERING—The Secretary of University Court, The University, Glasgow (April 22).

SENIOR LECTURER (graduate in veterinary science with postgraduate experience in bacteriology) IN VETERINARY BACTERIOLOGY at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, April 26).

POSTDOCTORAL RESEARCH FELLOW (organic chemist) IN CHEMISTRY—The Registrar, University College of Swansea, Singleton Park, Swansea (May 1).

SCIENTIFIC DIRECTOR (with a higher degree, preferably a doctorate, and considerable experience in marine zoology or a related experimental field) OF THE GREAT BARRIER REEF COMMITTEE'S RESEARCH STATION at Heron Island (University of Queensland)—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, May 3).

MICROBIOLOGIST/BIOCHEMIST (male, with a good honours degree and relevant postgraduate experience, preferably in biochemistry), to collaborate with plant pathologists in the study of host–parasite relations in fungal and bacterial diseases of fruit trees, particularly the biochemical factors associated with resistance—The Secretary, East Malling Research Station, Maidstone, Kent (May 6).

LECTURER OR ASSISTANT LECTURER IN THE DEPARTMENT OF ORGANIC CHEMISTRY—The Registrar, The University, Leeds 2 (May 25).

ASSISTANTS (honours graduates) IN THE DEPARTMENTS OF MATHEMATICS, PHYSICS AND CHEMISTRY—The Headmaster, Atlantic College, St. Donat's Castle, Llantwit Major, Glamorgan.

BACTERIOLOGIST (with a first- or second-class honours degree, and previous research experience), to carry out fundamental research in food microbiology; and a BIOCHEMIST (with a first- or second-class honours degree), for research on lipids in relation to food—The Secretary, Low Temperature Research Station, Agricultural Research Council, Downing Street, Cambridge.

CHAIR OF INORGANIC CHEMISTRY; and CHAIR OF THEORETICAL PHYSICS—The Registrar and Secretary, The University, Bristol.

CHIEF TECHNICIAN (with wide experience in either chemistry or biochemistry laboratories, the control of staff, maintenance and organization of laboratories and the purchase of equipment and materials) IN THE NEW DEPARTMENT OF BIOCHEMISTRY—The Secretary, Biochemistry Department, Imperial College of Science and Technology, London, S.W.7.

DEPARTMENTAL DEMONSTRATOR (preferably with some experience in either chemical analytical methods, emission spectroscopy, or X-ray crystallography) IN MINERALOGY IN THE DEPARTMENT OF GEOLOGY AND MINERALOGY—The Reader in Mineralogy, Department of Geology and Mineralogy, University Museum, Oxford.

MASTER TO TEACH CHEMISTRY at all levels—The Headmaster, School House, Rugby.

PRINCIPAL LECTURER; and a SENIOR LECTURER IN THE PHYSICS DEPARTMENT—Clerk to the Governing Body, Northern Polytechnic, Holloway London, N.7.

RESEARCH ASSISTANT (B.Sc., preferably with experience of radioactive isotope tracer work), to engage in studies of calcium metabolism in the Medical Unit—The House Governor, St. Mary's Hospital, Paddington, London, W.2.

RESEARCH ASSISTANT IN THE DEPARTMENT OF ANATOMY, for work on the electron-microscopy of cells in tissue culture—The Secretary, University College, Gower Street, London, W.C.1.

RESEARCH ASSISTANTS (honours graduates or students in their final honours year) IN CHEMISTRY, to work under the direction of Dr. W. Gerrard mainly in the field of organometallic and inorganic polymer chemistry—Dr. W. Gerrard, Head of the Department of Chemistry, Northern Polytechnic, Holloway, London, N.7.

SENIOR TECHNICIAN (with wide experience in the organization of chemistry or biochemistry laboratories) IN THE NEW DEPARTMENT OF BIOCHEMISTRY—The Secretary, Biochemistry Department, Imperial College of Science and Technology, London, S.W.7.

EMIGRATION OF SCIENTISTS FROM GREAT BRITAIN

FOR the past ten years the Advisory Council on Scientific Policy has from time to time expressed concern over the emigration of highly qualified research scientists, particularly to the United States, and the consequent effect on Britain's scientific manpower. An inquiry in 1954–55 showed that, during the academic years 1947–52, about 2 per cent of Britain's output of postgraduate chemists, among whom the loss was then thought to be most significant, had taken employment in the United States, but there was then no evidence that an undue proportion of the best graduates had left the country. In 1956 the Advisory Council sought further information, and the subject was fully discussed in the Council's report for 1956–57 and more briefly in its report for 1957–58. Since then, a Joint Board of the Civil Service Commission and the Atomic Energy Commission has been established to interview in North America candidates for Government posts in Britain, and this Joint Board is also interviewing candidates for research fellowships in universities and colleges in Britain offered by the Department of Industrial and Scientific Research.

Although conflicting views were frequently expressed as to the extent and seriousness of the loss of scientists to Britain, in view of the continuing shortage of scientific manpower the loss could not be ignored, and a year ago a report from the Institute of Physics and the Physical Society, listing 71 prominent physicists who had emigrated to the United States, expressed grave concern as to the effect on schools of physics in Britain (see *Nature*, 193, 911; 1962). In 1962 the Council of the Royal Society appointed an *ad hoc* Committee, with Sir Gordon Sutherland as chairman, to collect information on the subject. This report, covering the ten-year period up to May 1962, has now been published*. It is limited to scientists who were normally resident in, and who obtained a Ph.D. degree in, Britain. It is commendably brief, but it does not deal with immigration into Britain, and although a 96 per cent response was obtained from the 563 professors and other heads of departments who were consulted, its data are probably representative rather than comprehensive, nor does the report touch on the reasons determining either emigration or return to Britain.

The Committee concluded that the annual rate of permanent emigration of recent Ph.D.s is now at least 140 per annum, or about 12 per cent of the total output in anatomy, bacteriology and microbiology, biochemistry and biophysics, botany, chemistry, engineering, genetics, geology and geophysics, mathematics, metallurgy, pharmacology, physics, physiology and zoology. Of these, about 60 go to the United States, more than 20 to Canada, and 35 to other Commonwealth countries. This represents a three-fold increase in the decade, and, if those going abroad temporarily are included, the annual rate of migration of recent Ph.D.s to the United States is now at least 260, or more than 22 per cent of the output in the subjects investigated. The corresponding figures for all other countries are 157 or 13·5 per cent.

The annual rate of permanent emigration of university staff has also increased three-fold in the same period and is now about 60, or 1 per cent of the total staff in Britain in the subjects covered. Of these, some 25 go to the United States and about 25 to Commonwealth countries. The total permanent emigration of Ph.D.s and university scientists to the United States is thus at least 83 per annum in the subjects covered, and a recent report from the Natural Science Foundation, *Scientific Manpower from Abroad* (NSF-62-24), estimates the immigration of scientists and engineers from the United Kingdom in 1961 as 575, compared with 291 from Germany and 842 in 1957. Of these, about 400 are engineers and the figures include B.Sc.s and others. The decline in immigrants from the United Kingdom, however, is much less than that in immigrants from Germany, and it is probable that a significant percentage of the 1,200 scientists or engineers who enter the United States from Canada each year came originally from Britain.

Perhaps the most significant feature of the survey is the marked increase in the proportion of recent Ph.D.s on university staffs permanently emigrating to the United States; about 4 per cent of those awarded Ph.D.s emigrated in 1952, but the proportion rose to 8 per cent in 1957 and has remained steady at about 7 per cent in the past four years. Moreover, in the past five years Britain has lost a number of outstanding scientists to the United States, including nine Fellows of the Royal Society, and their departure has created gaps leading to difficulties in certain important fields of research in Britain. While the Committee did not obtain figures on the permanent immigration of scientists and engineers to the United Kingdom, it considers some balance might be struck between emigration to and immigration from the Commonwealth. Permanent immigration from the United States is negligible, and there is no suggestion anywhere in the report that the gross loss in quality is in any way discounted. What is certain is that the absolute emigration figures must be larger than those given in the report, although, since 36 out of the 475 departments to which questionnaires were sent failed to reply, certain ratios and annual comparisons may be slightly in error.

Over the decade the number of Ph.D.s going permanently to the United States has varied from 24 in 1952 to 61 in 1958 and the incomplete total for 1962 was 48. There is no doubt as to the marked upward trend of this emigration, and among chemists it has increased, on the average, by a factor of between 1·5 and 2, but even more among physicists. The emigration to other Commonwealth countries, which at least doubled in the same decade, included a large number of geologists, zoologists, botanists and biochemists, whereas chemists and physicists predominate in the flow to the United States.

Information on scientists with a Ph.D. degree who went abroad, mostly temporarily with a fellowship, etc., is less complete. Of 1,053 who did so (753 to the United States) in the five years 1957–61, 545 are known to have returned (410 from the United States), but the present location of 365 is uncertain. This temporary emigration to the United States is largely in chemistry and physics. Of the permanent loss of 389 university scientists, which increased from 19 in 1952 to 55 in 1961 and in 1962 was ~~64~~—a total known to be incomplete—the report observes that the loss to the United States was greatest in physics, chemistry, mathematics and biochemistry, in that order, and to Canada in chemistry and physics. Of the research institutions, the National Physical Laboratory, the National Engineering Laboratory, the Radio Research Station, the Services Electronics Research Laboratory, the Royal Naval Scientific Service and the Medical Research Council lost some 74 members of their scientific staff; this sample should discount the argument that conditions in the universities alone are inadequate to offset the attractions of the United States. Even in the Government service the 'drain' could be quite serious, and it would be rash to dismiss the argument of the Institution of Professional Civil Servants that this is to be attributed to short-sighted and illogical Government policy on remuneration for the Scientific Civil Service as without some justification.

---

* *Emigration of Scientists from the United Kingdom.* Report of a Committee Appointed by the Council of the Royal Society. Pp. 32. (London: The Royal Society, 1962.)

In its general remarks in this report, the Royal Society Committee, after examining figures from the University Grants Committee for 1960–61, expresses the opinion that Britain is probably losing nearer 19 per cent than 13 per cent of new Ph.D.s each year and that these include an unduly high proportion of the most promising scientists. Reports from the interviewing board of the Civil Service Commission and the Atomic Energy Authority expressed the view that some 70 per cent of those interviewed were worthy of appointments, compared with 50 per cent of those interviewed by the Commission in Britain. It is also noted that some 20 Fellows of the Royal Society now hold what are probably permanent appointments in the United States, of whom nine went there between 1958 and 1962, and that of the 224 university scientists who emigrated to the United States in the period 1952–62, 45 held senior professorships or are in charge of important scientific laboratories. The Committee notes in passing that this loss of scientists represents to some extent the loss of a considerable investment in education which, in a House of Lords debate on February 27, Lord Hailsham put at £20,000 or more per scientist, but it regarded as much more serious the economic consequences of the loss to Britain of the leadership and the creative contributions to science and technology which they would have made in the course of their working lives.

That, of course, is the crux of the situation and the real reason for the concern which was expressed alike last year in the report of the Institute of Physics and the Physical Society and in the debate in the House of Lords on February 27. The report, in fact, establishes the welcome fact that science is still incontrovertibly international. What is new is that the country which attracts the majority of migrating scientists is now the United States and not Germany, and consequently, so far as Britain is concerned, there is no longer in language alone one important factor favouring ultimate return to the country of origin. That the United States should have displaced Germany in this way is, nevertheless, not to be regretted in itself, and, if in due course the United States were succeeded by France or the U.S.S.R. or some other country as the lodestone, that should be to the advantage rather than the disadvantage of science as a whole. There is, in fact, very little that in short term a Government can do to affect the attractiveness of another country for its own scientists. In the long term, it can only aim at improving the excellence of the facilities available for its own scientists and to hope that in due course its own institutions may become something of a Mecca of science in their turn.

Ideally, of course, the institutions which provide the Meccas of scientists should vary from discipline to discipline in different countries, not simply because that situation might well provide a rough balance between emigration and immigration, but even more through the greater opportunities of cross-fertilization of ideas that could result. The growth of international institutions in science if wisely fostered could well contribute considerably to that end. Even as it is, the extent of the absolute loss is by no means easy to compute, and it is possible to write off much too hastily as a complete loss the £20,000 or so invested in the education of a scientist who permanently emigrates. Nor can one stress the vital importance of Britain's contribution to the development of the emerging territories and press for a larger contribution in education and research in those countries and at the same time claim that those who go overseas to serve those needs are no longer of any value to Britain. In any event, it is scarcely sound to argue that because a scientist has been educated at public expense he should remain *ipso facto* in the country responsible for it, particularly if there is any substance in the contention that the country is failing to provide appropriate opportunities or conditions of service commensurate with his ability.

Besides preserving some sense of proportion, it is obviously important that the Government should be clear as to the reasons which determine such emigration and be prepared to take whatever measures may, in the long run, help to restore a balance in numbers between emigration and immigration if, in fact, the loss is such as to threaten the staffing and efficiency of Britain's own institutions. It is one thing to say that it is immaterial where research is conducted since the results are available for all: it is another thing if difficulty is found in recruiting staff of the quality which the research institutions need or who are capable of attracting and inspiring students who, in turn, themselves will become leaders of research. It may, indeed, be a compliment to Britain that so many of her scientists should be sought by the United States, and Britain can be rightly proud of her record of Nobel prizewinners. That, however, should not induce complacency as to the maintenance of the conditions which, in the past, have fostered such excellence, or weaken the determination to do all that is possible to ensure that Britain produces an increasing number of such men and women whether they remain in Britain or not.

It should be noted that the Council of the Royal Society regards the report as purely fact-finding and does not propose to make any further comment on it at present. The Committee on Scientific Manpower is still considering a sample report from the 1961 census which indicated that there were some 40–50 per cent more scientists and technologists in Britain than had hitherto been anticipated. However, there is still no reason to believe that Britain is turning out enough scientists for her own needs; the Royal Society report clearly suggests that Britain is not providing sufficiently for the best. As to whether that is due to the absence of sufficient facilities is a matter of some dispute. Lord Todd, in his important speech in the House of Lords debate, was inclined to agree that this might be one factor, though he laid nothing like the stress on this factor that Lord Chorley did afterwards. Lord Chorley argued that the conditions of work, including equipment, was one of the decisive reasons determining emigration. Lord Chorley, incidentally, was inclined to argue that the other main reason was financial.

Prof. W. Mansfield Cooper has long since expressed strong disagreement with the view that either higher salaries or better facilities are dominant factors, but has been much more seriously concerned at the possible loss of outstanding young scientists because they find insufficient opportunities and prospects in Britain. This is a view freely reflected in individual comments on the Royal Society's report. It is widely believed that there is a lack of opportunities in Britain, and particularly that there are insufficient posts for creative work. It is also suggested that there is little enthusiasm for new ventures, a charge which is brought against industry as much as or more than against Government establishments.

Lord Todd wisely remarked in the debate that Britain could not hope to check emigration or restore a better balance between emigration and immigration simply by increasing her own postdoctoral fellowships. So long as the American economy kept expanding, the flood of American postdoctoral fellowships was likely to continue at its present level and Britain would suffer loss by emigration. He was disheartened, not because young scientists went abroad to widen their experience, but rather because so many sought it in the United States rather than in Europe, and he thought it would be worth a substantial effort to encourage more to go to Europe. He also directed attention to the element of chance which, as in his own career, might determine whether or not a scientist remained abroad, and pointed out that part of Britain's response in this situation must, in the first instance, be to seek to expand her economy and raise her national income. It was not simply a matter of providing more scope in the universities; a quickening of the pace and a change in the scope of research in Britain's industry might be even more important.

There is a further factor that deserves attention which was noted by Dr. I. W. Wark in an address last October on "Scientific Research as a Career" (see *Nature*, 197, 737; 1963). Dr. Wark, in discussing Australia's own problem of emigrating scientists, referred to the danger that the emigrating scientist might so make his changes even abroad as to acquire neither the variety of experience nor responsibility that would really fit him to exercise high responsibility. Dr. Wark expressed certain definite reservations with regard to overseas experience and study at the start of a research career which deserve serious attention, though it is difficult to see exactly what action could be taken on them officially. They are directed primarily at the Research Fellow himself, or at the departmental heads under which the research fellowship may be held.

One other point which was raised in the statement issued last year by the Institute of Physics and the Physical Society should also be considered. This is the frustration which is often experienced and the excessive time consumed in endeavouring to obtain grants for research projects. The Earl of Halsbury referred specifically to this in the House of Lords, instancing a recent observation by Prof. A. B. Pippard on the deteriorating morale in laboratories which resulted from delays, perhaps as much as six months, in obtaining grants for new apparatus needed to follow up a discovery. The Earl of Halsbury strongly supported Prof. Pippard's plea for some sort of discretionary fund placed at the disposal of the universities, but subject to subsequent audit and inspection, which would enable them to draw funds rapidly to permit swift response to new ideas. The statement of the Institute of Physics and the Physical Society advocated something similar, but was gravely concerned as to the ability of British universities at present to obtain adequate financial resources for new equipment and sufficient posts of responsibility. However, it recognized that British universities could offer a degree of freedom and a sympathetic atmosphere to new ideas comparable with those of the best Government and industrial laboratories in Britain, or even with American laboratories.

That, by implication, means a further look at the whole question of the administration of research, and the debate did, in fact, elicit a plea for a speedy report from the Trend Committee. Nor was this the only point at which the debate put the question of the emigration of scientists into its proper perspective. The Earl of Halsbury said frankly that it was most important not to do the right thing for the wrong reason. The real reason for making opportunities for young men was that it was the right thing to do. Britain should be a land of opportunity for the young, and the spirit of adventure should not be quenched, for such would only induce emigration; this view was strongly endorsed by Lord Hailsham in his reply on the debate. Britain should do whatever was necessary to improve science all the way through; she should improve her universities in size and pattern throughout, and thus make the whole quality of life more attractive.

Sir Gordon Sutherland and his colleagues have not written the last word on the emigration of scientists; rather they are likely to have stimulated an even closer debate on the reasons for emigration and the measures that should be taken, not to repress emigration but to ensure that Britain produces and retains a sufficient number of scientists of the highest ability to meet her own needs and those of the Commonwealth countries, including especially the emerging nations. It shows that science is still a truly international activity and that migration is to be welcomed not feared. What is to be feared is the short-sightedness, the parsimony and rigidity which fail to provide the conditions in which a creative activity can flourish and instead lead to frustration and waste of high ability. The importance of the inquiries now being conducted by the Trend Committee, the Slater Committee on research into natural resources and of that since initiated into the supply and use of technicians is again attested. Equally relevant are the findings of the Zuckerman Committee on the management and control of expenditure on research and development, and, it is hoped, those which the Robbins Committee is expected soon to make available.

In the face of all this material calling for close study and urgent imperative action, it would be reassuring to find the Minister for Science being equipped with larger and more commensurate staff for the purpose than loaded with fresh and essentially irrelevant responsibilities. When a responsible committee of physicists can express the considered opinion that, for the first time in Britain's scientific history, conditions in British universities are failing to attract physicists of the front rank the time for complacency—or flippancy—is past. Britain can no longer continue to rely on the elasticity of the arrangements in the past which have often proved so outstandingly successful, as, for example, in the creation of the Unit of Molecular Biology of the Medical Research Council with its recent Nobel prizewinners. If it is wise to await the result of the inquiries already in hand before modifying the present system, the facts revealed by this inquiry into the emigration of scientists attest the urgency of the situation and seem to point to one or two temporary expedients. What is essential is that the Minister for Science should make sure that, when the results of the present inquiries are at last available, decision and action should not be further delayed because it is found that further facts are required. Creative thinking should clear the way for swift action, including that of educating the public as to what is involved, in which the United States has in the past year or two made such striking and even revolutionary advances.

Moreover, the United States gives generous financial support to scientists and scientific institutions which not only stimulates, but sometimes also initiates, scientific advances and discovery not only in Great Britain but also in many other countries, both advanced and emerging. This is evidenced in practically every issue of *Nature*.

In other words, while recognizing that the recent Royal Society report should stimulate Britain to put her own scientific house in order (with an essential change of heart at the Treasury), it must be acknowledged that the United States is not only taking, in the form of scientific personnel, but also is generously giving, through her Foundations, Government departments, etc., and thus encouraging and supporting the advancement of science far beyond her own frontiers. This surely reveals the right attitude towards science as an international discipline which ignores national boundaries and differences in race, colour or creed.

MACHINES FOR HIGH-ENERGY NUCLEAR PHYSICS

Particle Accelerators

By Prof. M. Stanley Livingston and Dr. John P. Blewett. (International Series in Pure and Applied Physics.) Pp. xvi+666. (New York: McGraw-Hill Book Company, Inc.; London: McGraw-Hill Publishing Company, Ltd., 1962.) 135s. 6d.

THIS book is a welcome addition to the literature of particle accelerators. There are many excellent review articles on the subject varying from semi-popular expositions to highly technical treatises. Until recently, however, comprehensive books on particle accelerators have been almost non-existent. Yet the audience for such a book is wide, including as it does the accelerator physicist, the engineer, the nuclear physicist and to some extent the non-specialist.

In this respect the authors of *Particle Accelerators* have succeeded in producing a reasonable balance of all those aspects. Above all, they manage to convey something of the excitement and wonder which still adheres to accelerator building. To quote from their introduction: "The thrill of discovery is the reward of exploration", and again, "The pleasure and excitement of the working crew when a new accelerator is first tuned in to set a new voltage record is something to be remembered for a life-time". Comments like those and anecdotes, now part of the historical development of accelerators, give the book a warmth rarely found in treatises on technology.

Production of high-energy beams of charged particles in the laboratory began in the early 1930's with the Cockcroft and Walton d.-c. generator, the Lawrence cyclotron and the Van de Graaff electrostatic generator. Their impact on nuclear physics was tremendous and by 1940 these machines were commonplace in university laboratories. After the Second World War, the discovery of the principle of phase stability, a better understanding of dynamical principles, coupled with war-time advances in microwaves and electrical engineering, initiated a new family of large accelerators. These were the frequency modulated cyclotrons, the electron and proton synchrotrons and the betatron. There is no need to elaborate the significant contributions these accelerators have made in elementary particle physics during the past fifteen years. The largest of those accelerators are the *Bevatron* at Berkeley, and the 10-GeV machine at Dubna, near Moscow. Later this year similar machines will come into operation at the Rutherford Laboratory in Britain and at the Argonne Laboratory in the United States. This type of accelerator is now referred to as a constant gradient machine.

The success of these machines stimulated designers to seek new methods for increasing both the energy and intensity of existing accelerators. This search was rewarded by the discovery in 1953 of the principle of alternating focusing by Courant, Livingston and Snyder, and at an earlier date by Christophilos. Within the past few years three proton synchrotrons of this design have come into operation—a European machine at CERN, Geneva, of 25 GeV, an American machine at Brookhaven of 28 GeV and a Russian machine in Moscow of 7 GeV. The Russians are also building a 70-GeV machine which should come into operation in 1964. In addition, an electron machine of 5 GeV, directed by Livingston, has come into operation within the past few months. A similar machine should come into operation in Hamburg later this year.

This brief account of accelerator installations is only indicative of present-day activity in this field and does not include the very large number of smaller machines. Even so, the search for new techniques still goes on. This has led to a new family, still in the design stage, now referred to as fixed-field alternating gradient accelerators. Design studies in extending the range of the present alternating gradient machines also suggest that these could be extended to 1,000 GeV with a diameter of several miles. The pressure to build such a machine is likely to grow rapidly in the near future.

This 'story' of accelerator development is very well told in the present book. Both authors have participated in the advances of this field and have an intimate knowledge of many of these machines. Livingston, for example, was associated with Lawrence in the early 1930's in cyclotron development. After the War he helped to design the *Cosmotron* and the *AGS* at Brookhaven, and recently has directed the electron synchrotron project at Cambridge, United States. Blewett has also been associated with the construction of both the *Cosmotron* and the *AGS*. In particular, he has been responsible for the proton linear accelerator injector and for directing recent design investigations in a large international accelerator project.

In their book, separate chapters are devoted to each type of accelerator mentioned here. There are also special chapters on ion sources, particle dynamics, the principle of phase stability, magnet design and shielding. A strong sense of historical development accompanies the description of each machine, which makes enjoyable and stimulating reading. The amount of detailed information recorded by the authors is quite remarkable. In a subject which has always demanded a happy alliance between physicist and engineer the authors have succeeded in giving due weight to each. To the specialist in one or other of these fields the style may at times be too racy, and certain aspects may be treated rather superficially for the book to be a satisfactory formal text-book, but what it lacks in this respect it gains in information and enthusiasm. It is a book that everyone associated with accelerators, as designers, as builders or as users, will profit from and enjoy reading.

W. Walkinshaw

COAGULATION OF THE BLOOD

Human Blood Coagulation and Its Disorders

By Dr. Rosemary Biggs and Dr. R. G. Macfarlane. Third edition. Pp. xxiv+474. (Oxford: Blackwell Scientific Publications, 1962.) 52*s*. 6*d*. net.

THE five years since the last edition of this book have brought a greater clarity to the field of blood coagulation: it has not been necessary to postulate the existence of any new clotting factors, but much light has been shed on the inter-relationships of those factors the existence of which in normal blood is now firmly established. Important recent work has been concerned with the activation of the coagulation mechanism by contact of blood with glass and other foreign surfaces, the changes which platelets undergo during clotting, the relationship of thrombosis to coagulation and the fibrinolytic system. All these developments are lucidly and critically discussed in the new and extensively revised edition of this excellent book.

The form of the book remains unaltered: the first part is devoted to the theoretical aspects of human blood coagulation and the second to the diagnosis and treatment of coagulation defects. There is an excellent new introductory chapter to the second part which will enhance the value of the book to the practising physician and clinical pathologist, and the technical appendix has been amplified. The most important practical advance in the treatment of blood coagulation disorders in recent years has been the authors' own work on the preparation and clinical use of concentrates of antihæmophilic globulin and Christmas factor, and the use of these is fully described.

It is a pleasure to record that the standard of production is vastly improved. In spite of the inclusion of much new material, the book has been kept to the same size, partly by the use of slightly smaller print and by the omission of the summaries at the end of each chapter, which served no very useful purpose in the previous editions. The figures are now excellent and the bibliography is greatly improved by being collected in a single alphabetical series; only the index leaves room for considerable improvement in subsequent editions. This book remains unchallenged in its field; it is not only indispensable to all workers on blood coagulation, but also so well balanced and readable as to be highly recommended to non-specialists.

R. M. Hardisty

TISSUE TRANSPLANTATION

Ciba Foundation Symposium on Transplantation

Edited by G. E. W. Wolstenholme and Margaret P. Cameron. Pp. xii+426. (London: J. and A. Churchill, Ltd., 1962.) 56*s*.

THIS volume is dedicated to the memory of the late Peter A. Gorer, whose brilliant work on the serology and serological genetics of homograft reactions is briefly surveyed in the Chairman's opening remarks. In closing these remarks Prof. P. B. Medawar states "... let us not forget that we are still quite ignorant of the proximate cause of the death of any homograft" and "... we know of no harmless and lastingly effective way to subdue the homograft reaction in adult animals".

The sixteen papers presented at this symposium contain little that offers immediate hope of negating these statements although obvious progress is being made in the understanding of some of the immunological aspects of tissue transplantation. The opening papers deal with the considerable recent progress made in the difficult problem of identification and characterization of tissue antigens. Further practical progress is reported in the attempts to ameliorate runt disease in mice. Notable contributions to the theoretical advance are the papers presented on the role of the thymus, the quantitative nature of immune tolerance and an investigation into the clonal selection theory.

In view of the increasingly successful efforts being made in the field of human organ transplantation, it is disappointing to find that, with one exception, the communications are confined to studies on small rodents. Nevertheless, the symposium is of obvious value to any worker in the field of tissue transplantation, as a convenient summary of recent progress in the non-clinical aspects of this subject.

W. J. Dempster

NATURAL AND SYNTHETIC COLOURING MATTERS

Recent Progress in the Chemistry of Natural and Synthetic Colouring Matters and Related Fields

Edited by T. S. Gore, B. S. Joshi, S. V. Sunthankar and B. D. Tilak. Pp. xxvii+659. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 171*s*. 6*d*.

THE book contains a collection of papers and reviews most of which deal with recent progress in the chemistry of natural and synthetic colouring matters, but a few are concerned with the wider field of plant chemistry and general organic chemistry. The authors in many cases are of world-wide reputation, both in the field of theoretical and experimental organic chemistry. Some of the papers follow the pattern of those found in the journals of the various chemical societies, with the exception that all the authors start with a reasonable introduction to their subject-matter, a thing which is rarely found in some present-day journals, thus making it easier for the reader to follow and understand the work under discussion. Some of the papers even go so far as to include an experimental section along with analytical results. In the reviews, a particular field is surveyed over a number of years and in the majority of cases right up to 1960. In many instances suggestions are made for further investigations which still require to be carried out in the reviewed field.

About one-third of the book is devoted to the chemistry of oxygen heterocyclic and related natural occurring compounds, while a quarter deals with various interesting synthetic dyes and intermediates, the preparation and properties of which, in a number of cases, are treated from a physical chemical point of view. I am pleased to note that the editors have not allowed the reviews concerned with the chemistry of dyes to become pages of recipes. Other parts of the book are concerned with some topics found in the following fields; the azulenes, diterpenes, alkaloids and carcinogenic hydrocarbons. The book succeeds in presenting an up-to-date and complete account of the included topics in the light of modern theory, the subject-matter being presented in a clear and concise fashion. In a book of this type it is quite easy for the editors to omit a topic which some readers might believe should have been included, but I think that they have made a very good selection.

Though most of the book is concerned with up-to-date work, the occasional review describes some older significant and outstanding work in a particular field, especially among some of the naturally occurring pigments, an example being the work of Hooker on the chemistry of lapachol. A few pages are even devoted to Hooker himself, an extraordinary man and a true master of experimental investigation.

It follows, therefore, that the potential market for this book will be limited, but for specialists in the fields mentioned, and for libraries it will provide a valuable summary of information and a worthy addition to the literature of organic chemistry. It will also be of interest to some students specializing in organic chemistry, as well as to chemists and technologists concerned particularly with synthetic dyes. The overall production is excellent, and the diagrams and formulæ are clear and easy to follow. This book was compiled to commemorate the contribution to organic chemistry of Prof. K. Venkataraman on the occasion of his sixtieth birthday.

R. LIVINGSTONE

HISTORY OF THE INTELLIGENCE TEST

Studies in Individual Differences

The Search for Intelligence. Edited by James J. Jenkins and Donald G. Patterson. (The Century Psychology Series). Pp. xiv+774. (London: Methuen and Co. Ltd., 1961.) 63*s*.

THIS volume brings together for the first time sixty-six previously published papers, covering the historical development of intelligence testing. The authors range from Sir Francis Galton (1869) to Dr. Guilford (1959). In terms of its professed aims—that of helping students—the collection must be judged a success; nowhere else can so many formative contributions be read with such ease.

Nevertheless, it is a sobering moment when a research field commemorates its ancestors in this way, and one which invites more general comment. First impressions are undoubtedly favourable. Almost all these articles reflect a high level of technical competence; and some of them, Spearman's for example, are works of virtuosity. Second impressions are less comforting. We are reminded of how long ago our present methods of testing were established, and how little we have added during the past forty years to our knowledge of their practical value. By the end of the First World War, intelligence tests were already established as valid instruments of general classification. Fryer (1922) shows, for example, that there is relatively little overlap in intelligence quotient between "dentists" and "labourers", between "clergymen" and "sheet metal workers". Since 1922, the mental testing movement has expanded out of all recognition, and there has been a luxuriant growth of theories about the structure of the intellect, but our tests and our knowledge of their predictive efficiency are in most essentials the same as they were when Fryer's article was written. By normal technological standards then, this is an area of conservatism, even of stagnation.

Another disconcerting impression is one of dullness. Thinking is presumably the human being's most interesting accomplishment, so it must be of some significance that, in our efforts to measure it, we have generated a literature of such tedium. Throughout its considerable length, this volume contains barely a handful of references to individual people tested—although Terman's work is an important exception in this respect—and even fewer instances of their thinking in real life situations. Indeed, in some of the more recent articles, scarcely a shred of human subject-matter remains. In view of the statistical sophistication that mental testers nowadays take for granted, this suggests not merely a neglect of natural observation but an actual flight from it. Paradoxically, it seems, the study of human thinking has become a haven for the kind of scientist who finds it natural to have as little personal contact with the people he tests as possible. The dangers of such a situation are obvious. Individuals, particularly those who are exceptions to a given rule, are invaluable to psychologists as a source of criticism. Their loss of interest in individual people may thus account not only for the dullness of the intelligence tester's work but also its conservatism.

Surprisingly early on, intelligence testers seemed to lose the inventiveness which characterized early pioneers like Binet. Covertly, they seemed to assume that all the essentials of intelligence could be measured with the tests to hand. Yet the briefest glance at the intelligence quotients of any group of successful brain-workers—research physicists for example—would have shown them that this was false. Many brilliantly successful men and women have relatively unimpressive intelligence quotients; many who succeed brilliantly at intelligence tests are relatively unimpressive in every other respect. It follows, at the higher levels at least, that the measurement of intelligence is an area crying out for innovation.

LIAM HUDSON

CIRCUMPOLAR PLANTS

The Circumpolar Plants

1. Vascular Cryptograms, Conifers, Monocotyledons. By Eric Hultén (Kungl. Svenska Vetenskapsakademiens Handlingar, Bd. 8, No. 5). Pp. 275. (Stockholm: Almqvist and Wiksell, 1962). 65 kronor.

PROF. HULTÉN is well known to everyone interested in phytogeography for the excellent distribution maps he has published of the plants of north-west Europe and, more recently, for his work on amphi-atlantic plants. In all these maps a great deal of information is conveyed with remarkable clarity by means of a combination of shading, individual symbols and lines.

The present volume is in a sense a continuation of the one dealing with the amphi-atlantic plants and follows the same general plan; in fact, as Prof. Hultén himself observes, no clear distinction can be drawn between the amphi-atlantic and circumpolar types of distribution.

The species included range from those, such as *Colpodium vahlianum*, which are nearly confined to the arctic, to others, for example *Adiantum capillus-veneris*, which reach their northern limit in England. They all have wide, though often strongly disjunct, distributions in the northern hemisphere.

In general, a broad view is taken of what constitutes a species and not infrequently the areas of groups of closely similar species are shown on one map. This practice has the advantage of bringing out certain features of circumpolar distribution, some of the most striking of which are discussed in the introduction. The discontinuities, it is suggested, are partly due to climatic preferences and partly to historical factors, such as the former existence of a large ice-dammed fresh-water lake in the Obi Basin. The not infrequent occurrence of a fairly uniform series of populations in the north paralleled by a ring of distinct subspecies or closely related species on mountains much further south is very plausibly explained in terms of climatic changes during the Quaternary period.

It is evident that over large areas information about the flora is inadequate so that both distributional data and taxonomy are unsatisfactory. This is a limitation which has to be accepted for the present, and it is to be expected that these maps will provide a stimulus for further work.

There are inevitably errors and omissions in a work of this size, even in regions the flora of which is as well known as that of the British Isles. Perhaps the most striking of these is in the map of *Potamogeton natans*, where only four localities, all in the extreme north, are shown though the plant is, in fact, recorded from every part of the country. Two other less obvious but perhaps more serious errors are the inclusion of records for *Eriophorum alpinum* and *Carex bicolor* from Scotland, neither of which is now accepted as correct.

These are, however, minor blemishes in a valuable and well-produced work, which would be more convenient to use if the pages had been cut by machine.

T. G. TUTIN

IONOSPHERIC CONSEQUENCES OF THE EARTH'S ORBITAL ECCENTRICITY

By Sir EDWARD APPLETON, G.B.E., K.C.B., F.R.S.
Principal and Vice-Chancellor, University of Edinburgh

THE Earth moves in an elliptical orbit and is therefore not always equidistant from the Sun. The Earth–Sun distance is, in fact, 3·4 per cent greater in early July than it is in early January, at which latter period the Earth makes its closest annual approach to the Sun. The result of this orbital eccentricity is that solar electromagnetic radiations, as received on the Earth, are 6·5 per cent weaker in early July than in early January. The effect of this annual variation of solar radiation intensity is, of course, small, and cannot be detected in measurements of, say, atmospheric temperature because of the influence of large-scale air movements. A recent attempt to detect the effect on the ionosphere has, however, been successful.

The stratum of the ionosphere selected for examination was the E Layer, because of the known regularity of its behaviour. This is an ionospheric layer in which the rates of electron production and electron loss are sensibly equal, so that the electron density of the layer is in a quasi-stationary condition[1]. This is especially the case at noon, and that is why noon measurements of peak electron density alone were used in the search for an annual effect.

The raw material used in the investigation has been the corpus of regular ionospheric measurements made, over recent years, by the world's ionospheric stations. More specifically it consists of measurements of the hourly critical penetration frequency of the E Layer, fE, as disclosed by the method of vertical radio sounding; since, from this quantity, it is possible to calculate the peak electron density of the E Layer, $N_m(E)$. In order to discover whether the annual variation of the intensity of the incoming solar ionizing radiation was recognizable in the measurements of $N_m(E)$ it was necessary to ensure that such measurements referred to a constant value of the Sun's zenith distance, χ, throughout all the months of the year. This meant that noon measurements of peak electron density made at a fixed site were unsuitable, because of the change of the value of χ at that site with the season. Instead, it was necessary to use measurements from a large number of stations all over the world and plot curves showing the dependence of $N_m(E)$ on χ, for noon conditions during each month. From such curves there could be read off the values of $N_m(E)$ for any selected value of χ for any particular month.

Another feature of the treatment of the data consisted in removing the influence of the variation of sunspot activity from month to month during the course of the year. In a subsidiary investigation it has been found that $N_m(E)$ increases substantially proportionally to increase of R, the Zurich sunspot number. This result prompted the suggestion of using the average value of $N_m(E)$ for the eleven years of a sunspot cycle as the representative value for a given hour of the day in a given month. Two advantages accrue from such an operation. In the first place the effect of the variation of R from one month to the next has been sensibly eliminated; while, secondly, there has been a statistical advantage in using more data in the inquiry. The sunspot-cycle period selected for this averaging process consisted of the years 1949–59 inclusive, and so included the period of the International Geophysical Year, 1957–58. In addition, it was found that, for the year 1954 exceptionally, the value of R was extremely small and roughly constant over the months of the year. It was therefore possible to make an additional search for the annual effect using the results of this one year only.

By using the averaged results for the period 1949–59, or the results for the year 1954 alone, it was possible, then, to find the value of $N_m(E)$ for each month of the year, under both constant-χ and constant-R conditions. In this way one might hope to detect an annual variation of $N_m(E)$ resulting from the annual variation of the ionizing flux of radiation, now thought to be solar X-rays, which is responsible for the E Layer formation.

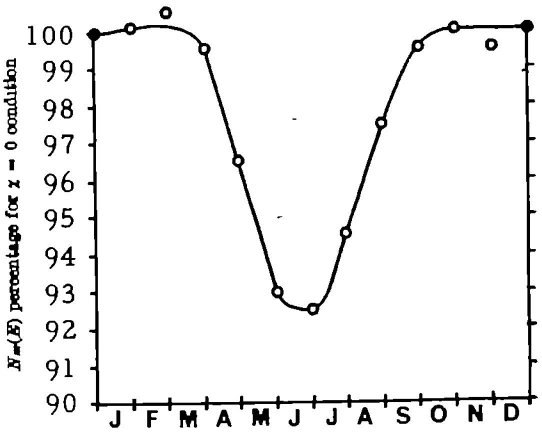

Fig. 1 Relation between the peak electron density of the E Layer, $N_m(E)$, and the month of the year, for vertical-Sun conditions

In Fig. 1 are plotted the various values of $N_m(E)$ for the sunspot cycle 1949–59 under conditions of constant χ and constant R. The values are expressed as percentages of the average value for December and January, since the Earth approaches closest to the Sun on January 3. Evidence of the expected annual effect is at once recognizable, the value of $N_m(E)$, under conditions of both constant χ and R, being less during June–July than during December–January. As is stated in the legend to Fig. 1, the values of $N_m(E)$ for each month relate to conditions of vertical Sun, that is, $\chi = 0$. This choice was made to eliminate any possible effect of a purely seasonal character. The average value of the Zurich sunspot number, throughout the months of the year, for the period 1949–59 was roughly 90, a figure about half that representative of sunspot maximum conditions.

Since the curve depicted in Fig. 1 portrays an annual variation of the type we should expect, due to the Earth's orbital eccentricity, we are encouraged to compare the magnitude of the effect found in the E Layer with that to be expected on theoretical grounds. As has already been stated, we know that the intensity of the solar ionizing rays must be 6·5 per cent less during June–July than during December–January. Undoubtedly, therefore, the rate of electron production in the E Layer will follow an annual variation of the same magnitude. But the value of the resulting ionospheric electron density depends on the rate of electron loss as well as on the rate of electron production. If the rate of electron loss is describable by an attachment law, for example, we should expect $N_m(E)$ to vary directly with the intensity of the solar radiation flux. If, on the other hand, electrons disappear according to a recombination law, we should expect $N_m(E)$ to vary as the square root of the intensity of the solar flux. In the former case we should expect an annual effect, in $N_m(E)$, of 6·5 per cent; in the latter case of 3·25 per cent. Now it happens that the experimental results shown in Fig. 1 indicate an annual variation of 7·5 per cent, which might be taken as indicating the operation of an attachment law. Other investigations, however, suggest that the law describing the rate of electron loss in the E Layer is one intermediate between that of attachment and recombination, in which case the experimentally observed effect is larger than that wholly attributable to the Earth's orbital eccentricity.

The general result of the investigation reported here must therefore be that the effect of the annual variation of the Earth–Sun distance has been shown to be recognizable in ionospheric measurements; but the existence of a smaller additional annual variation, due to some unknown cause, cannot be entirely excluded.

---

TOWARDS A SOUTHERN COMMONWEALTH OBSERVATORY

By Dr. S. C. B. GASCOIGNE
Mount Stromlo Observatory, Canberra, Australia

THE arguments for setting up a major optical telescope in Australia, possibly under joint United Kingdom–Australian control, have received much recent publicity and are well known[1]. Briefly, they are that from Australian latitudes one can see the third of the sky inaccessible to northern observatories, this third containing such strategic objects as the Magellanic Clouds and the galactic centre; and that if progress is to be made with the tremendous problems created by the radio astronomers it is essential that the Commonwealth Scientific and Industrial Research Organization radio installation at Parkes, New South Wales[2], and the large Mills cross being built at Hoskinstown[3], be matched by a reasonably equivalent optical facility—the 210-ft. dish has already far outstripped the capabilities of the 74-in. telescope at Mount Stromlo. These arguments are strong, much more so than may generally be realized; a telescope of the size proposed, 120 or 150 in., could make a decisive impact on astronomy, one out of all proportion to its size and cost. My purpose is to show why this is so.

Two problems at the heart of present-day astronomy, and two to which a considerable part of the time of this telescope would be devoted, are those of evolution and magnetic fields. Evolution has been a preoccupation with astronomers for the past hundred years, but real progress has been possible only since the recognition, explicitly by Bethe in 1938, of the thermonuclear conversion of hydrogen to helium as the primary source of stellar energy. Since then the subject has developed rapidly; now we can estimate ages for galaxies, clusters and for many individual stars; we have a reasonable idea of how stars are formed, evolve and decay; we can suggest processes by which heavier elements are built up from hydrogen, and see how stellar and interstellar matter may be steadily enriched by the creation of these heavier elements. Equally, the subject abounds in unsolved problems: What are the dynamics of star formation? How do stars evolve in their later stages? What is the place of variable stars in the evolutionary scheme? How do we explain the abnormal chemical abundances which continually seem to be cropping up? And so on.

Magnetic fields in galaxies were unknown fifteen years ago. Their existence was first suggested by consideration of cosmic-ray energies, then by observations of interstellar polarization, but the recognition of their true importance had to wait for Shklovsky's work in 1953 on synchrotron radiation—the emission of electromagnetic radiation by high-energy particles spiralling in magnetic fields. The synchrotron process not only explains, in a unified way, the broad features of interstellar polarization, galactic coronal emission and cosmic rays, but also provides the major clue to our understanding of radio galaxies like Cygnus A, and of spiral structure, a spiral arm being perhaps nothing more than a gigantic tube of magnetic force. It is now clear that magnetic fields are intimately concerned with the structure and dynamics of galaxies—the magnetic and kinetic energies of our galaxy, for example, are roughly equivalent—and we begin to see how, given the mass, angular momentum and magnetic energy of a galaxy, we may be able to trace its evolutionary history and so see how galaxies have become differentiated as regards both structure and stellar content. To achieve this understanding is an ultimate goal of astronomy; and there seems no place where it can better be attained than in the Magellanic Clouds. It is here that we hope to gain the overall view, the correlation of evolutionary processes with morphological and dynamic features, as well as the detailed insight into the outstanding evolutionary problems themselves. What some of these problems are, and where progress is held up for want of more telescope power, I will now describe.

The Magellanic Clouds are near—ten times nearer than the Andromeda nebula—and rich in neutral hydrogen, emission nebulæ, super-giants, peculiar stars, variables of all kinds, young clusters and old clusters, all these objects—an important point—at much the same distance from the Sun. It is because of this that the Clouds provide such an unparalleled opportunity for investigating evolutionary processes. From the young clusters we can find the present rate of star formation, and learn something of the factors such as density, turbulence and dust content of the pre-stellar medium on which the actual process of star formation is believed to depend. One need here is for radial velocities of individual cluster stars. From the old clusters we can, in principle, determine both an age and an approximate chemical composition, and so build up a picture of how element formation has proceeded in the Clouds. We may be able to go further, and answer such questions as: Are the Clouds younger than the galaxy? How long have they been associated with the galaxy? Progress here depends rather critically on our ability to measure magnitudes and colours for stars of 20th magnitude or fainter; at present we cannot reach to much below 19, and it is difficult to see how this figure can be improved.

Better abundance determinations can be made from analyses of stellar spectra, taken at high enough dispersion (~ 15 A/mm); but with existing spectrographs (which are as efficient as any) such spectra can be obtained only for very luminous stars in the Clouds, and these, because of their super-giant characteristics and resulting instability, are unsuitable for abundance determination. Variable stars have always played a central part in astronomy, as indicators of distance, and, more recently, of the age and evolutionary status of the populations in which they occur. The Magellanic Clouds contain thousands of variables; again, some of the most critical, the short-period cluster variables, are just above the limit of detection of a 74-in. telescope, and can be investigated only slowly and with difficulty. Finally, an optical, as distinct from a 21-cm kinematic, picture of the Clouds can be built up from spectroscopically determined radial velocities of Cloud stars, and this is essential to any understanding of the large-scale structure. In the galaxy we have radial velocities for about 12,000 stars; in the Clouds, for 200, each the product of several hours' work on a 74-in reflector. Here the need is not so much to go fainter as for a more rapid accumulation of data.

Important though the Magellanic Clouds may be, the basis on which all stellar astronomy rests is detailed studies of the much nearer objects in the galaxy, and most of the work of the northern observatories is directed towards this end. The southern third of the galaxy has, of course, its share of objects of special interest, either as prototypes or prime examples of a particular class, or because they exhibit peculiar or significant properties (in astronomy the peculiar is almost always significant). These objects include some unique gaseous nebulæ, especially the Gum and Eta Carinæ nebulæ; three of the brightest cepheids in the sky, all with unusual properties; hundreds of open clusters; the majority of the globular clusters; and innumerable peculiar stars, single or multiple. One of these, an extraordinary object, appears to consist almost entirely of hydrogen and rare earths, with a small admixture of inert gases and calcium. I mention it first because it is unique, and presents astrophysicists and nuclear physicists with one of their most formidable problems in this field; secondly, because of the limitations of existing telescopes we cannot observe it at high enough dispersion to enable us to determine the atmospheric parameters which are essential to any theoretical discussion.

There are, of course, problems peculiar to the southern part of the galaxy as such. We want to delineate the major structural features, especially the spiral arms; to map the galactic field; to explore the kinematics of the galaxy to greater distances and in greater detail; and to determine the distance and something of the nature of the galactic centre. Here, as in the preceding section, existing equipment is more adequate, and much progress has been made. But the kinematic problem—in this context the measurement of the radial velocities of remote galactic objects—will always require the greatest telescope power available, and the results are essential to the proper interpretation of the 21-cm observations being made at Parkes. Progress on the galactic centre, which in Australian latitudes passes through the zenith, is also much to be desired, especially since the radio astronomers have shown this to be a region of most unexpected complexity. Even with a major telescope, however, there will be difficulty in penetrating the dust clouds which lie between us and the galactic centre.

Passing now beyond the local system, the most challenging problem, and indeed one of the most exciting in modern physics, is that presented by the radio galaxies. A typical source, Cygnus *A*, radiates 10^6 times as much radio power as a normal galaxy, though at visible wavelengths the powers are comparable; it is about 300,000 light-years across—twice the distance from the Galaxy to the Magellanic Clouds—and contains, in the magnetic field and associated particles, the energy equivalent of 10^8 supernova explosions, an appreciable part of the available nuclear energy of the whole galaxy. Ten years ago a suggestion that such an object actually existed would have been dismissed as preposterous. Now we regard it as a magnetic field stretching far into intergalactic space, together with a source which can inject into it colossal numbers of relativistic particles, the particles, of course, supplying the radiation by the synchrotron process. The problems of the origin and maintenance of the field, and the energy supply of the source, are completely unsolved. Most radio galaxies have a complex structure, which seems to bear little resemblance to that of the optical galaxies with which they are identified. As is well known, this identification is a matter of great difficulty, even for the formidable northern combination of the Cambridge and Owens Valley interferometers and the 200-in. telescope. To match the appreciably more powerful Parkes and Hoskinstown installations, at Mount Stromlo we have only the 74-in. reflector. Already it is clear that quite powerful radio sources can barely be detected with the 74-in., let alone examined in any sort of structural or spectroscopic detail. Nevertheless, it is largely from such identifications and such investigations that progress must come. As Burbidge remarked of the synchrotron process: "The key arguments leading to our theoretical understanding came from predictions and observations of the *optical* radiation from the Crab nebula and the jet in M 87". (The italics are his.) Australia has here the opportunity of achieving a historical advance in a field it has made peculiarly its own. It would be a national tragedy if this opportunity were allowed to pass to one of the countries already known to be planning their own large southern telescopes.

Two questions remain. First, will the development of image intensifiers make large telescopes unnecessary? The short answer is that an image tube promises to be effectively a high-speed photographic plate, fast enough to cut exposures by a factor of 10 or 100. As such, its major immediate application will be in spectroscopy, where it promises to effect a revolution. The detection of faint stars and galaxies is another matter, governed by the joint effects of the brightness of the night sky and of photon statistics, and in this field it will be much longer before the image tube can compete with the photomultiplier, a virtually noiseless device of equally high quantum efficiency. The cost of developing such a tube will be comparable with that of a great telescope.

The second question is: Will satellites make terrestrial observatories obsolete? In one sense this has already been answered by the planning and active construction of a number of major telescopes, most of them either in the United States or the U.S.S.R. The first satellites are to observe that part of the ultra-violet spectra of bright stars and interstellar matter which is inaccessible from the surface of the Earth; this task can be done in no other way. When it comes to the measurement of faint stars and galaxies near the limit of big optical telescopes the position is different. The satellites are now competing directly with conventional telescopes. They will have the advantages of dark skies and small images (small because they will be undisturbed by atmospheric variations), but to capitalize on these must overcome enormous technical problems, just one of which will be the necessity for maintaining pointing accuracies in the region of 0·01 sec arc over extended periods. Difficulties mean money, and while the point has been made before, one cannot refrain from mentioning that the Venus probe (there were two) is reported to have cost £10,000,000. This sum would pay for an observatory of the scale advocated here at least twice over; the scientific return from the observatory will surely be many thousands of times greater.

ARE CRYPTOVOLCANIC STRUCTURES DUE TO METEORITE IMPACT?

By Prof. WALTER H. BUCHER*
Consultant, Humble Oil and Refining Co., Houston 1, Texas

THIS article is a brief summary of the main geological argument contained in a detailed paper on cryptovolcanic structures which is to appear in the *American Journal of Science*. In view of the present lively interest in possible evidences of meteorite impact it is important to make available the areal setting of major cryptovolcanic structures which casts serious doubt on the present tendency to ascribe their origin to meteorite impact.

The term 'cryptovolcanic' was applied in 1905 by Branco and Fraas[1] to the small, circular Steinheim Basin in south-west Germany. In 1933, I (ref. 2) described essentially

* Professor emeritus of geology, Columbia University.

similar, but more deeply eroded, roughly circular structures in the United States, and reviewed the evidence concerning three others which are only incompletely exposed. Since then, other comparable areas of intense local deformation have been discovered. The second edition of the *Tectonic Map of the United States* marks the location of 14 cryptovolcanic structures[3], but more have come to light since it was published.

These structures consist of: (1) a central uplift within which the strata are highly contorted and broken up, surrounded by (2) a more or less continuous ring-shaped depression which tends to be bounded and cut by faults. In the Steinheim Basin, this depression is concealed by fresh-water lake deposits. Branco and Fraas ascribed the origin of the Steinheim Basin to volcanic activity. Some of the intensely shattered limestones within the central hill are full of peculiar cone-shaped bodies representing conical fracture surfaces densely covered with bifurcating ridges and grooves which radiate from the top of the cone. Because of this highly characteristic pattern, the authors called these bodies "Strahlenkegel", interpreting them as products of violent shock. I found similar shatter cones in the centre of the largest of the American cryptovolcanic structures, the Wells Creek Basin[4]. Since 1933, the idea that cryptovolcanic structures might be the result of meteorite impact has steadily gained favour among American geologists[5]. Suspecting that shatter cones might be used as evidence of shock from above, Dietz visited the majority of the American cryptovolcanic structures and found that shatter cones are present in most of them. By a bold jump in logic, he suggested that shatter cones may be diagnostic of meteorite impact[6].

His reasoning received unexpected and powerful support from the discovery of coesite and stishovite in the Ries Basin[7]. Coesite and stishovite are heavy phases of silica. They occur in minute amounts in the glassy phase of 'bombs' of partially fused gneissoid and granitoid basement rocks which abound in deposits of suevite, a tuff-like rock made up of comminuted silicate materials and glass shreds. The Ries Basin, the largest known European circular structure of problematic origin[8], differs from the typical cryptovolcanic structures in having no central uplift and no shatter cones. Instead of the central uplift, there is a deep, roughly circular depression from which all overlying sedimentary rocks (Permian to upper Jurassic) and several hundred feet of the crystalline basement have been removed and scattered over the surrounding basin shelf and on to the undisturbed surface of the surrounding plateau, in a mixture of large fragments up to hill-size in a matrix of finely ground rock powder. Where the floor of the surface on which this 'Bunte Breccie' rests is exposed it is covered with scratches and grooves which point toward the centre of the structure. Shattered rock masses and 'Bunte Breccie' lie scattered up to a distance of 20 km (12 miles) from the outer rim of the basin (or 29 km (18 miles) from the edge of the central depression), the average size of the fragments growing finer with distance. Reich's detailed seismic refraction studies[9] have shown that the floor of the central circular depression, with a diameter of 8 km, is essentially flat.

The structure of the broad ring-shaped 'shelf' between the edge of the surrounding undisturbed plateau and the central depression is largely hidden beneath a thick blanket of fresh-water limestones deposited in a lake formed when the outlet of the valley of the Wörnitz River was filled with ejecta from the Basin. (Remnants of this fill still cling to the valley side below the town of Harburg.) Reich's seismic studies suggest a disordered mosaic of blocks of concealed pre-Tertiary rocks on either side of a horseshoe-shaped ridge of displaced gneissoid basement rock, perhaps a 'damped-wave' effect like that suggested by the structure of the Wells Creek Basin[10]. In the Ries, however, the central part was blown out, not merely boosted up. The most striking aspect of the Ries Basin is thus the superficial character of the disturbance. Drilling in two cryptovolcanic structures in North America indicates that there, too, deformation was limited to shallow depths.

The roughly circular outline with the greatest deformation in the centre, the violent disruption of the rocks in the centre, the shallowness of the disturbance, common association of shatter cones with cryptovolcanic structures, other structural features suggesting origin through shock, such as narrow fissures filled with rock powder, and above all, the presence of high-temperature–high-pressure phases of silica, all find such a simple and elegant explanation in meteorite impact that geochemists and geophysicists, and a rapidly growing number of geologists, tend to assume the problem solved.

No doubt most, if not all, geochemical and geophysical (tectonic) features of individual cryptovolcanic structures could have been produced by meteorite impact. But were they? Discussion based on these features neglects a fundamental point: If meteorite impact created the structures, their incidence in time and space must be consistent with the hypothesis, that is, they must be distributed at random. This means that they must not bear any demonstrable relation to structural axes in the Earth's crust, nor to features the formation of which was accompanied by deep-seated volcanic activity.

In the forthcoming paper, I apply this test to the largest cryptovolcanic structures of Europe, America and Africa: the Ries Basin, the Wells Creek structure, and the Vredefort Dome (accepting the application of the term 'cryptovolcanic' to this structure by supporters of the hypothesis of meteorite impact).

The choice of the largest example in each continent is independent of any structural considerations and makes use of the outstanding examples quoted by the advocates of origin by meteorite impact—in the Ries Basin especially because of the presence of coesite and stishovite in the partially melted gneissoid fragments in the suevite tuff associated with it, in the Wells Creek Basin and the Vredefort Dome because of the conspicuous development of shatter cones. In all three cases, inspection of the regional setting reveals conclusively that each lies on a major regional structural axis aligned with one or several structures involving localized mafic and ultramafic igneous rocks.

Fig. 1 shows three essentially circular structures lined up in south-western Germany at intervals of approximately 50 km: the Ries Basin (21–24 km in diameter) with coesite in glass from partially molten basement, the Steinheim Basin (3·5 km in diameter), the type locality of shatter cones, and the Urach region (about 40 km in diameter) where more than 250 tuffisite pipes perforate the Jurassic plateau like a sieve. In the Urach area, most of the pipes are filled with finely ground-up rock material (chiefly limestone) with varying proportions of lapilli of melilite basalt; basalt occupies a few of the pipes[11].

The line connecting these three unusual areas essentially parallels: (1) the axis of a geomagnetic high which reflects a gentle buried pre-Triassic topographic ridge; (2) the axis of the young flexure along which the Mesozoic rocks of the Jura Plateau of southern Germany bend down beneath the Miocene and younger rocks of the Swiss foreland of the Alps. On the map (Fig. 1) this is shown by the shoreline of the marine upper Miocene sea which can be recognized to-day as a distinct low marine cliff, with pholadid borings and layers of barnacle fragments in the adjoining marine beds. Moreover, two facts link the Ries with the other two structures aligned with it: (1) all three structures came into being in uppermost Miocene time, a time of widespread volcanic activity in western Europe; (2) drill holes in both the Ries Basin[12] and the Urach area[13] reveal a geothermal gradient almost three times as great as that which is normal for western Europe, and as high as that of Thermopolis, Wyoming[14] (which is some 145 km (90 miles) from Yellowstone Park, famous for its young volcanism and active geysers).

Fig. 1. Map of the structural axis on which lie the Ries Basin, Steinheim Basin and the Urach area of breccia pipes. (Data from Georg Wagner (ref. 28); Gerold Wagner (personal communication); Neumann (ref. 29); Reich and Horrix (ref. 9); Carlé (ref. 13))

Yet two of these structures, the Ries Basin and the Steinheim Basin, are supposed to be the result of the impact of a giant meteorite and a minor satellite respectively, while the Urach region is the product of deep-seated volcanic activity.

The hypothesis of meteorite impact demands that by pure chance two meteorites, a giant accompanied by a satellite, hit the Earth in line with a wholly independent major terrestrial structural axis precisely at a time when volcanism was active throughout western Europe, and that the larger of the two, also by chance, produced by impact approximately the same amount of heat as that of the volcanic Urach region so that, after some 6–8 million years, the thermal gradient is as great to-day as that around Thermopolis, Wyoming.

The Wells Creek Basin stands out among American cryptovolcanic areas by its size (diameter about 13·7 km = 8·5 miles); by the intensely broken up condition of the rocks in the uplifted central area which form a veritable megabreccia; and by the poorly developed, but distinct, anticlinal ring between the outer limits of the structure and the central uplift, suggestive of an elastic damped wave effect[15].

The Wells Creek Basin is aligned with two structures, the Hicks Dome and the Avon area, along a prominent anticlinal flexure zone comparable with that which connects the Ries and Steinheim Basins with the Urach area. In Fig. 2 (ref. 16) this curved axis is left blank. To the north, the Pennsylvanian formations dip very gently north-north-eastward into the Illinois Carboniferous basin. To the south, the Cretaceous–Tertiary formations dip equally gently into the head of the Mississippi embayment. In the centre of this curved flexural axis, opposite the head of the embayment, lies the Hicks Dome, an oval, faulted, domed area of about 14·5 km (9 miles) average diameter, characterized by breccia pipes and dikes rich in mafic to ultramafic volcanic material (one dike carries radioactive yttrium–thorium monazite)[17]. From Hicks Dome, dozens of thin, more or less vertical breccia dikes with varying amounts of basic volcanic material cut the Mississippian rocks in a south-south-easterly direction, on top of and parallel to the axis. The size of the small mafic dikes south-south-east from Hicks Dome is greatly exaggerated in Fig. 2 (ref. 16) in order to make them stand out. They seem to end at the southern border of the detailed geological map of the western Kentucky fluorite district, from which the representation is taken[16]. They grow smaller south-south-westward, but may well extend farther than shown on the map.

About 145 km (90 miles) to the south-south-east of the Hicks Dome, three diminutive craterlets filled with Cretaceous sediments trend north-north-westward a short distance beyond the Wells Creek Basin, that is, essentially in the same direction as the basic dikes farther north, and, more important, in the direction of the anticlinal flexure zone (Fig. 2). Dr. Wilson[18], who described them, called them impact craters, caused by small meteorite fragments running ahead of the master meteorite. Here, as in the Ries–Steinheim–Urach line, it is assumed that a giant and baby meteorites hit the ground in line with the axis of an independent major flexure zone.

About 168 km (105 miles) west-north-west of the Hicks Dome lies the Avon area[19]. It is broadly oval, with the long axis measuring about 17·5 km (11 miles) and, surprisingly, it duplicates the Urach area. So far, 78 breccia pipes have been found. All are quite small, some contain only ground-up limestone fragments in a limestone powder, like some in the Urach region; but most of the pipes contain fragments of granitoid rocks carried up from the basement together with lapilli of melilite basalt which are practically identical to those of the Urach region[20]. Through the courtesy of its chief geologist, Dr. Frank G. Snyder, I have been able to examine the cores from two holes drilled by the Saint Joseph Lead Company in the Avon area. The increase in basaltic lapilli and in granite fragments downward is strikingly shown as the drill holes approach the crystalline basement and, in one case, penetrate it deeply.

Here then, of three structures lying on a major flexure zone (of purely terrestrial origin), one is supposed to be the product of meteorite impact, while the other two are undoubtedly volcanic in origin.

I cannot accept a hypothesis which holds that in two continents multiple meteorites (in one case a giant and a

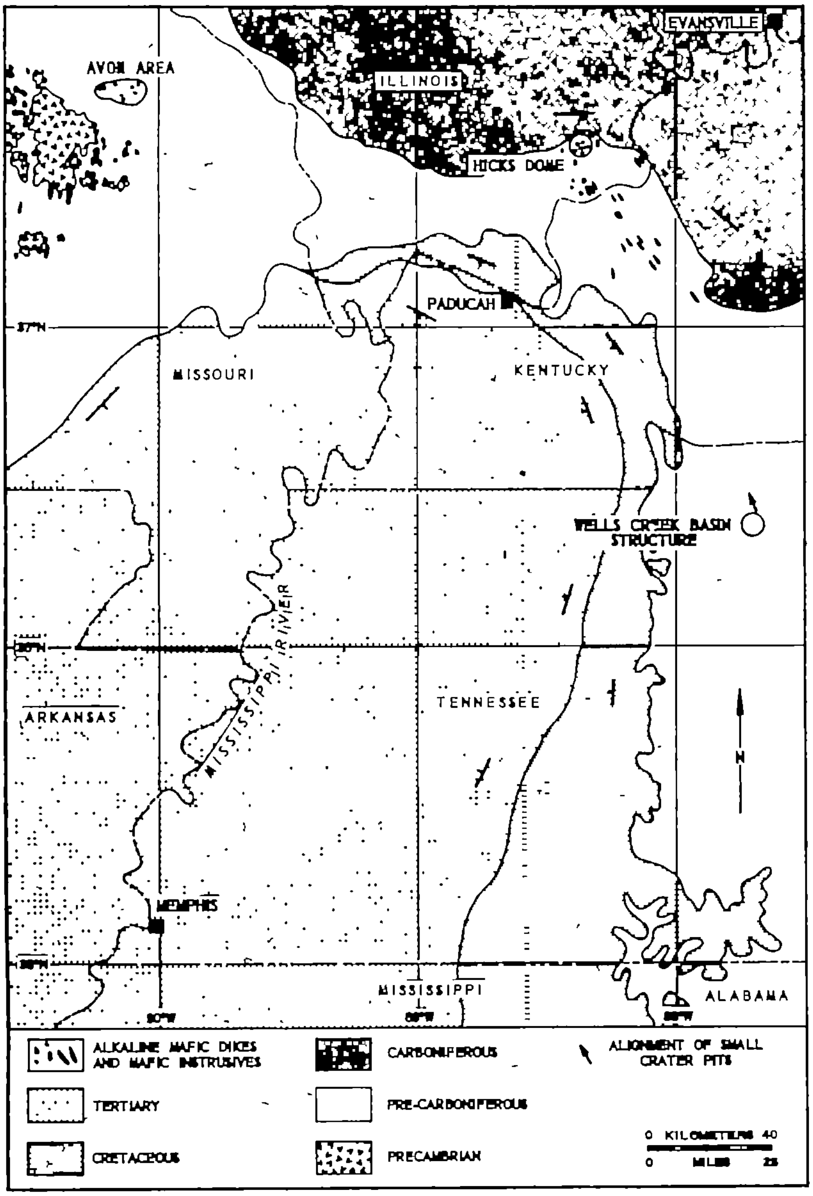

Fig. 2. Map of the structural axis on which lie the Wells Creek Basin, the Hicks Dome and the Avon area of breccia pipes. *Note*. Only the location of the structures and of mafic alkaline dikes (exposed or cut in drill holes), breccia pipes and the trend of three diminutive crater-like pits are shown. All structural details, especially the complex fault system of the Illinois–Kentucky mining district, are omitted. (Data from Heyl and Brock (ref. 16); Kidwell (ref. 19); and the *Tectonic Map of the U.S.A.*, second edit. (ref. 3))

satellite, in the other a giant and dwarf fragments) struck a clearly defined terrestrial flexure zone so that their impact scars are aligned parallel to its axis and with structures of proved volcanic origin.

Like the largest cryptovolcanic structures of Europe and America, the Vredefort dome lines on a major structural axis, but one of a wholly different nature. Fig. 3 (ref. 21) shows that it is one of four roughly circular areas (points 4–7) in the Orange Free State which lie on a straight line over 430 km (270 miles) long, trending toward the centre of the vast Bushveld area (point 3), in a north-north-easterly direction (about N. 27° E.). In Southern Rhodesia, a second structural axis (points 1 and 2) trends a little more northerly (N. 17° E.), also heading toward the centre of the Bushveld intrusive centre. This is the Great Dyke, one of the great ultramafic terranes of the Earth's surface. The total distance from the northern end of the Great Dyke to the Trompsburg structure (points 1–7) is more than 1,450 km (900 miles).

The Great Dyke[22] is a relatively straight-layered body of mafic and ultramafic rocks, over 530 km (330 miles) long and between 5 and 11 km (3–7 miles) wide. It was intruded into a terrane of crystalline rocks, chiefly granite, with occasional zones of metamorphic schists. Intrusion proceeded from four centres, each producing a sequence of similar structure and component rock types, but differing from each other in the number of layers, their thickness and distribution. In each complex, the component layers maintain a remarkably constant average thickness. All dip toward the centre of the Great Dyke from their borders, while longitudinally they plunge toward the centre of eruption in each complex.

Where seen in a few good exposures and confirmed by inclined drill holes that passed from the rocks of the Dyke at the surface into the granite at depth, the borders of the Great Dyke are fault contacts dipping inward at angles varying from 25° to 70°. On either side, the Great Dyke is paralleled by a long quartz gabbro dike which disappears where the central portion of the Dyke is most depressed. These companion dikes seem to be the last phase in the regional differentiation process.

In length, width and even in the northerly trend, the Great Dyke resembles the complex young grabens of the East African graben belt. These young grabens, of course, are much wider at the surface. But with border faults converging downward toward the base of the crust at angles averaging 45°, perhaps to a depth of 10 km or more in earlier Precambrian time, the border faults of the Great Dyke would converge to something like 4 km from a possible surface width of 24 km. Near the base of the crust, where the faults would tend to become merely boundaries between plastically moving rock masses, the ultramafic rocks of the sub-crust would tend to rise isostatically in response to the lowering of the surface of the graben. Repeated intrusions of ultramafic materials into the base of the sinking graben block seem feasible in view of the plastic rather than the viscous conditions of rock at moderate depth. The ultimate synclinal structure may be the result of final compaction and settling of the cooling rock body, perhaps combined with a last sagging of the graben.

The coarse grain of the ultramafic rocks requires crystallization beneath a roof of substantial thickness. Remnants are preserved in bodies of schists measuring up to three miles across, where the Dyke cuts belts of metamorphosed sediments.

Recently a comparable complex was discovered[23] in the Zambesi valley, about 128 km (80 miles) west of the Great Dyke. It is some 40 km (25 miles) long and consists of rocks similar to those in the upper layers of the Great Dyke.

The Bushveld complex[24] of intrusive sheets and connecting dikes which lies at the centre of this vast alignment of mafic and ultramafic rocks (point 3), is about 400 km (250 miles) wide east to west, and not much less in a north–south direction. The combined thicknesses of these intrusions amount to 6–8 km (4–5 miles), wedged between layers of the thick Transvaal system (15,000–28,000 ft.); the lower horizons carry the same concentrations of platinum and chromium that are found in the Great Dyke.

The Trompsburg structure in the Orange Free State at the far end of the southern line of intrusives (point 7) is roughly circular, and, from the size of the gravity anomaly, its diameter is estimated to be 48 km (30 miles)[25]. It was first discovered by the high gravity and magnetic anomalies above it. Drilling showed that it contains the same mafic and ultramafic rocks which characterize the whole belt; the same was proved for the minor intrusions (points 4 and 6 on Fig. 3).

The Vredefort dome lies neatly in line with the whole belt of deep-seated intrusions. The high positive gravity anomaly above it indicates that heavy rocks underlie the unbroken roof of granite and infolded metasediments. The joint patterns on the exposed granite surfaces are those seen generally on broadly domed basement areas[26]. But the granite and overlying mantle of sediments are traversed by an intricate network of pseudotachylite veins—anastomosing dikelets of pulverized basement rocks, comparable with similar veins in the Ries, where they cut basement and sediment cover. Shatter cones—which are missing in the Ries—are found in abundance in most rock formations of the Vredefort dome[27].

Fig. 3. The Bushveld chain of intrusives (redrawn from Cousins, ref. 21)

To assume that a giant meteorite happened to strike a point precisely in line with structures produced by such large-scale deep-seated magmatic activity within the same general (earlier Precambrian) time interval, producing a structure of similar dimensions 35 km (22 miles) away, seems to me to carry the original hypothesis *ad absurdum*. In the case of the four cryptovolcanic structures discussed here, the hypothesis of meteorite impact seems, therefore, unacceptable. It follows that neither the presence of shatter cones nor of heavy phases of silica are criteria for meteorite impact. The full paper will discuss possible alternatives.

SOME MICROSTRUCTURES OF COMPLEX MORPHOLOGY OBSERVED IN PREPARATIONS OF CARBONACEOUS CHONDRITES MADE UNDER STERILE CONDITIONS

By Dr. GREGG MAMIKUNIAN and Dr. MICHAEL H. BRIGGS*

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

VARIOUS classes of microstructures in the 5–30µ size-range have recently been examined in samples of carbonaceous meteorites by Claus and Nagy[1–3], who have named the objects "organized elements". On the basis of detailed morphological studies and staining reactions with biological dyes, Claus and Nagy have suggested that the "organized elements" are microfossils of an extra-terrestrial life-form, indigenous to the meteorite parent-body.

Other workers who have also investigated samples of these meteorites and have identified structures that they consider to be indigenous fossil remains are Staplin[4], Reimer[5], Palik[6,7], Cholnoky[8], Skuja[9], Ross[10], Engels[11] and Timofeev[12].

---

* Resident Research Fellow.

On the other hand, several scientists, after examining the structures in question, have claimed that identification as microfossils is premature. Thus Fox[13] has suggested that the objects are spheroids of non-biological organic matter, together with droplets of sulphur and contaminating terrestrial organisms.

Fitch *et al.*[14–16] have argued that the "organized elements" are various mineral grains and hydrocarbon droplets together with some contaminants. Deflandre[17] has similarly claimed that the objects are terrestrial contaminants or artefacts. Briggs[18], who examined sterile preparations of the meteorites, has suggested that some are mineral grains, while others are associations of sulphur with organic matter, probably of abiogenic origin. In a recently prepared report[19], we have identified what we believe to be terrestrial contaminants in sterile meteorite preparations. Mueller[20] has presented evidence that one class of "organized element" which displays a complex morphology is a rare limonite pseudomorph of troilite.

With this marked disagreement it is clear that the true nature of the "organized elements" will be solved only after prolonged examination by many different scientists competent in various fields. Thus, contributions from bacteriologists, palynologists, micropaleontologists, pathologists, crystallographers, histologists and organic chemists are necessary, and it is improbable that any single person is competent to identify microscopic objects in all these fields. As the meteorites are difficult to obtain and are only available for examination at present by a small group, we have prepared a catalogue of microphotographs[21] for wide circulation.

Table 1. DETAILS OF METEORITES

Name	Country of origin	Date of fall	Wiik's (1956) classification (ref. 22)
1. Orgueil	France	1864	I
2. Cold Bokkeveld	South Africa	1838	II
3. Murray	United States	1950	II
4. Haripura	India	1921	II
5. Mighei	Ukraine, U.S.S.R.	1889	II
6. Mokoia	New Zealand	1908	III
7. Felix	United States	1900	III
8. Dimmit	United States	before 1947	non-carbonaceous

Table 2. STERILIZATION PROCEDURE: PERCENTAGE ETHYLENE OXIDE AND RELATIVE HUMIDITY IN STERILIZING GAS MIXTURE

Position and time (h)	Percentage ethylene oxide	Temp. of ethylene oxide (°F)	Dew point (°F)	Percentage relative humidity
0	27·7	70·5	+49·5	46
1	27·5	72	+49	44
3½	27·6	75·5	+47·5	37
4½	27·8	72·5	+47	40
5¼	27·3	74	+50·5	43
5½	26·6	76	+51	41

In this article we present a selection of photographs of some microstructures of complex morphology which we have observed in sterile preparations of some of the meteorites.

A list of meteorites used in this investigation is given in Table 1.

All meteorite samples were examined to ensure that they were free of fusion crusts, museum markings and obvious surface contamination.

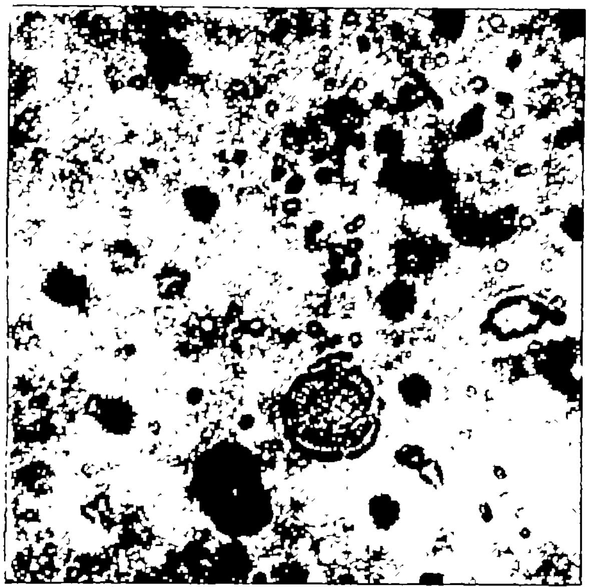

Fig. 1. Microstructure observed in Mokoia meteorite preparation. (× 630)

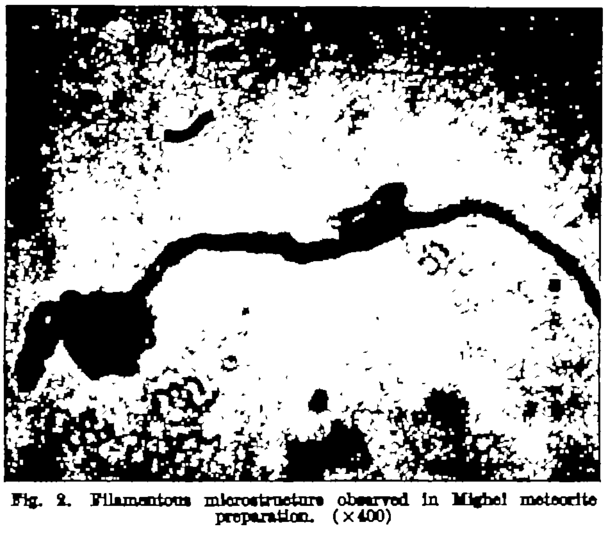

Fig. 2. Filamentous microstructure observed in Mighei meteorite preparation. (×400)

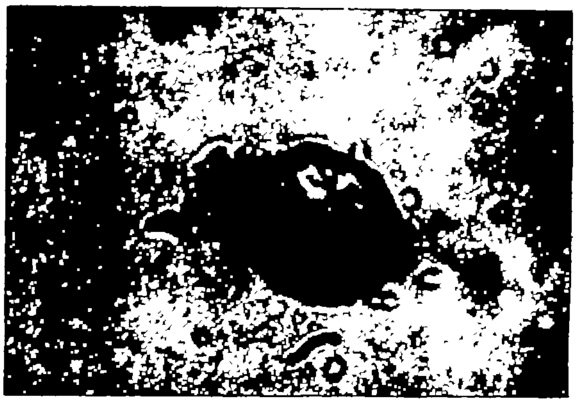

Fig. 3. Microstructure observed in Haripura meteorite preparation. (×630)

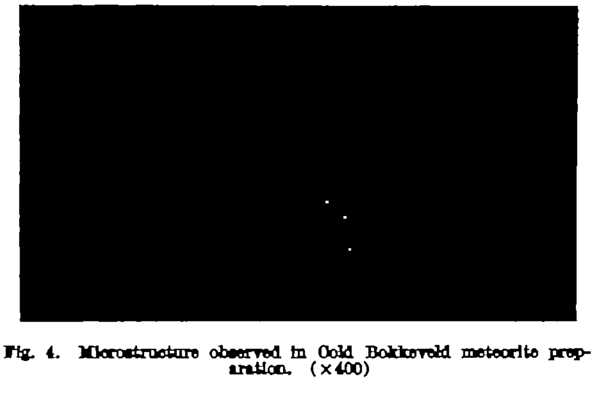

Fig. 4. Microstructure observed in Cold Bokkeveld meteorite preparation. (×400)

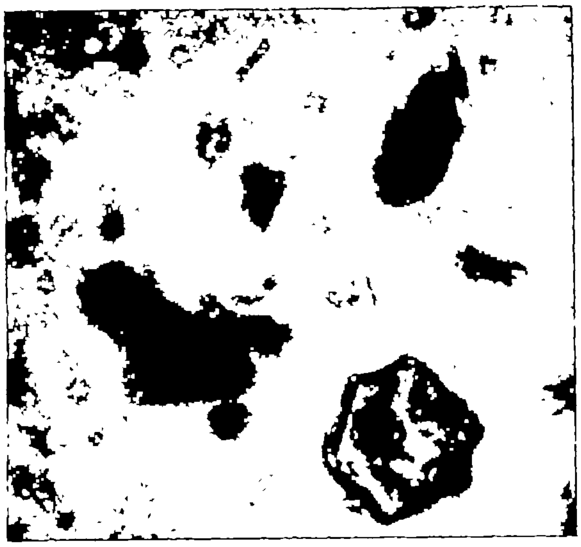

Fig. 5. Microstructure observed in Cold Bokkeveld meteorite preparation. (×630)

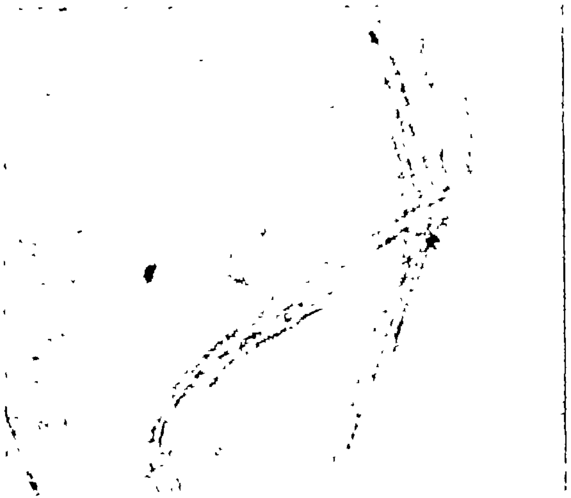

Fig. 6. Filamentous microstructures observed in Dimmit meteorite preparation. (×400)

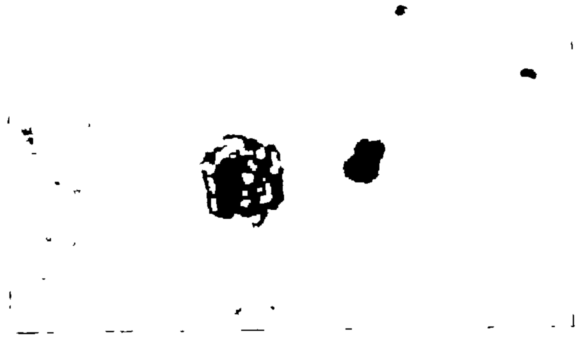

Fig. 7. Microstructure observed in Orgueil meteorite preparation (×1,000)

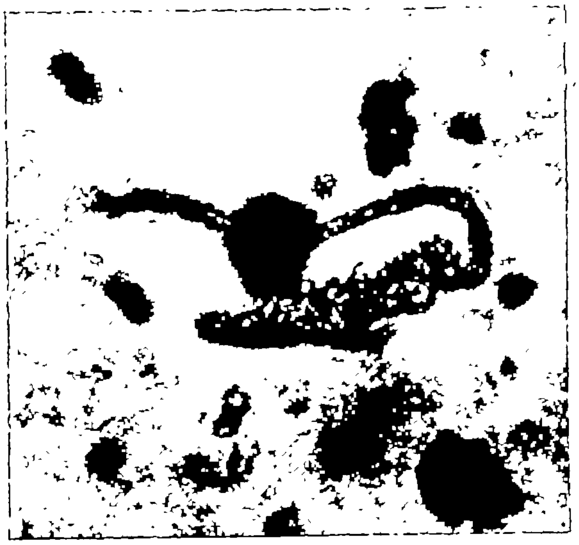

Fig. 8. Microstructure observed in Orgueil meteorite preparation. (×630)

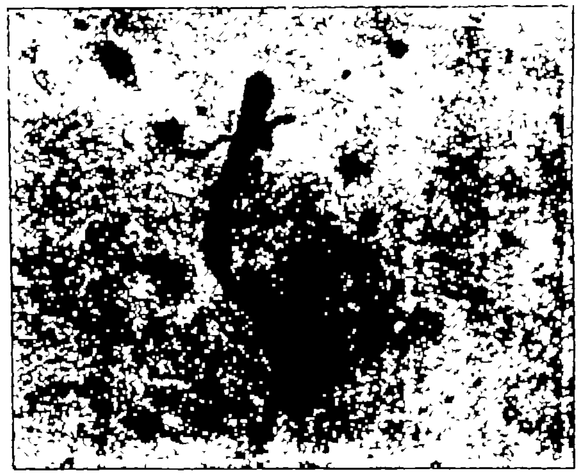

Fig. 9. Microstructure observed in Murray meteorite preparation. (×160)

Small pieces of each meteorite were separately placed in Petri dishes in a sterile glove-box. All other equipment used in preparation was also placed in the box. The interior of the box was then sterilized by ethylene oxide for 5·75 h. Table 2 shows the sterilizing conditions at intervals throughout this period. Ethylene oxide was removed by flushing with sterile nitrogen for 30 min. Microscope slides were prepared in the atmosphere of nitrogen.

All slides were prepared in the same manner. A small grain of meteorite was carefully powdered between glass slides, then mounted in 'Permount' beneath a coverslip. Six slides were prepared of each meteorite. Other slides were stained with saffranin or crystal violet before mounting. Control slides were made of the stains and 'Permount' without meteorite powder.

The remaining grains of meteorite were added to separate steril containers of 'Trypticase' growth medium, which were then sealed and incubated for 7 days at 37° C. After this time no growth was detected in any container.

Photomicrographs of some interesting structures observed in these preparations are shown in Figs. 1–10.

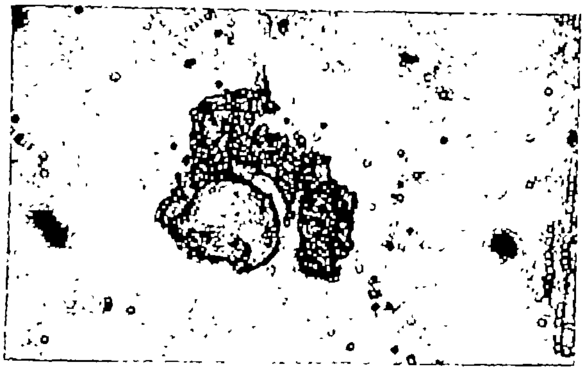

Fig. 10. Microstructure observed in Mighei meteorite preparation. (×400)

An examination of these illustrations demonstrates that all meteorite preparations used in this work contain a variety of rare microstructures in the c. 20-μ size-range which exhibit a complex morphology, and yet are not readily identifiable. It is our opinion that most of these objects are unusual mineral grains or terrestrial materials which have contaminated the meteorite during museum storage. However, conclusive identifications are not possible.

We thank the following for gifts of meteorite samples: Dr. W. A. Watters, New Zealand Geological Survey; the Director, Wanganui Museum; Dr. E. P. Henderson, Smithsonian Institution; Dr. E. Anders, University of Chicago; Dr. R. Marshall, Jet Propulsion Laboratory; the Director, Indian Geological Survey; the Director, Chicago Natural History Museum.

We also thank Mr. F. Morelli, Jet Propulsion Laboratory, for help in the preparation of slides.

SPECIAL THEORY OF RELATIVITY

By PROF. HERBERT DINGLE

THE replies which have been received to my communication to *Nature*[1], in which I pointed out a contradiction in the special theory of relativity, are too numerous for individual publication, and the Editor has asked me to deal with them (other than that of Prof. Max Born, which appears on p. 1287 of this issue) collectively. Apart from trivial misunderstandings, the criticisms of my argument fall into a few classes which I will consider separately, but I should first say that only one correspondent heeds the last paragraph of my letter, despite its italics. I there asked, not for the reason why Einstein's statement differed from mine, of which I was aware, but why the former should be considered true and the latter false. The correspondent in question—the only one, in my view, who has really faced the problem—admits that no such reason can be found, and concludes that the conception of an objective rate–ratio of two clocks is impermissible. I cannot agree, but since space prohibits an analysis of this suggestion I justify my dismissal of it here by the fact that I am examining only Einstein's theory, and since he asked: "What is the rate of this clock, when viewed from the stationary system ?" and gave an answer in "seconds per second", it is clear that he accepted a rate–ratio as a meaningful conception.

The remaining correspondents make the following points (it will be remembered that my communication contained two statements, one by Einstein claiming that moving clocks run slow, and one by me claiming that moving clocks run fast): (1) In Einstein's statement the interval considered is that between the separation of the clocks and an event on the moving one, but mine refers to the interval between the separation of the clocks and an event on the stationary one. I have therefore myself introduced the contradiction which I ascribe to Einstein's theory. (2) The internal consistency of the Lorentz transformation can be demonstrated mathematically; it is therefore unquestionable. It gives a unique value for the time of every event in every inertial co-ordinate system, and so cannot possibly contain a contradiction. This reply is usually accompanied by a Minkowski diagram. (3) Both statements show how one clock appears to an observer on the other; they are not contradictory because they relate to different co-ordinate systems.

None of these replies meets the point of my criticism. I can best explain this, I think, by slightly amplifying the situation as described by Einstein, so as to make explicit some steps there tacitly assumed and make the situation more vividly imaginable.

$$\dot{Y} \rightarrow \underset{A}{.} \qquad\qquad \dot{X} \rightarrow \underset{B}{.}$$

A and X are twins who separate at birth at a speed v such that $\sqrt{(1 - v^2/c^2)} = 1/5$. Each carries a clock which reads 0 at the moment of separation and thereafter reads the age of its bearer. Ahead of A, in the direction of X's motion, and keeping at a constant distance from A, is another child B, born at the same moment as A in A's and B's common time system and carrying a similar clock synchronized with A's. Likewise, in the rear of X, and keeping at a constant distance from X, is a child Y, born at the same moment as X in X's and Y's common time system and carrying a similar clock synchronized with X's.

When X is 6 years old he passes B and they exchange photographs which have just been taken. B, and therefore A, is then 30 years old according to the Lorentz transformation. Further, when A is 6 years old Y passes him and they also exchange recent photographs. The Lorentz transformation then shows that Y, and therefore X, is then 30 years old. All assemble later and agree, on the evidence of the photographs, that A is 30 when X is 6 and X is 30 when A is 6. I call this a contradiction.

The readings can be set out in more detail: Tables 1 and 2 readily follow from the Lorentz transformation.

Table 1 corresponds to Einstein's statement, with A fixed at the origin of the K system and X at the origin of the k system, and we see that X ages more slowly than A, as he concludes. But we also have Table 2.

Table 1

		X is born	X meets B
'Stationary' (K) system	t =	0	30
'Moving' (k) system	τ =	0	6

Table 2

		A is born	Y meets A
'Stationary' (K) system	t =	0	6
'Moving' (k) system	τ =	0	30

Table 2 corresponds to my statement, with A and X still fixed at the origins of the same systems as before, and we see that A ages more slowly than X.

I can now deal with the above objections.

(1) Of course I have referred to a different pair of events from Einstein; vain repetition would be foolish. If a thing has contradictory aspects, you will not discover the fact merely by inspection of one, however often repeated. Einstein's statement and mine are neither paraphrases of one another nor two halves of a single argument. They are independent statements, running in parallel, not in series, and if one is valid, so is the other; but they lead to incompatible conclusions. There is no reason why the persons or clocks should be compared by Table 1 rather than Table 2. True, I do not get X's age directly but have to infer it from Y's; but Einstein does not get A's age directly but infers it from B's. If Y's photograph is not evidence of the age of X, thus discrediting my conclusion, then B's is not evidence of the age of A, thus discrediting Einstein's. It seems to me self-evident that any objection to the implications of Table 2 is *ipso facto* an objection to the corresponding implications of Table 1.

(2) The internal consistency of the Lorentz transformation is not in question. The figures in both tables, as the Minkowski diagram shows clearly, are unambiguous, and not, as numbers, conflicting; but no clock or person can behave in such a way as to fulfil their requirements. One correspondent urges that Einstein's theory is that the time of a distant event can be assigned only by definition and not by natural necessity, and a definition cannot be disproved. But that is not Einstein's theory; that merely clears the ground to make room for a theory (it was, in fact, at the time a piece of supreme intellectual insight). If that were all, then any fantastic figures could appear in the tables, and could not be disputed. But Einstein proposed a particular definition, and his theory was that actual clocks would conform to it. It required them to behave so that the figures in each horizontal line of Tables 1 and 2 were the readings of clocks synchronized according to his prescription, and those in each vertical line were related by the Lorentz transformation. That determined them uniquely. This was, and is, too difficult to test experimentally when it differs perceptibly from the Galilean requirements, but what Tables 1 and 2 show is that the clocks cannot conform to the theory, for in order to satisfy some of its requirements (Table 1) they must necessarily violate others (Table 2). Hence the theory fails—not because of mathematical inconsistency but because of inapplicability to the facts of nature.

(3) This point is met in my reply to Prof. Born (p. 1287); there has been no change of co-ordinate system. But, in any event, co-ordinate systems are merely means to an end; the contradiction here is in the end. Suppose A and B are black and X and Y white. Then what is proved is that blacks are men when whites are boys, and blacks are boys when whites are men. You do not change their skins when you bring them mentally to rest.

An analogy will pinpoint the problem. To find the effect of latitude on clock-rate I use two clocks differing only in latitude. Calculation then shows me that A reads 11 o'clock when B is observed to read 10, and that B reads 11 when A is observed to read 10. Neither clock goes backwards. I conclude that the calculation is wrong. Substitute 'uniform motion' for 'latitude' and 'special relativity theory' for 'calculation', and the analogy becomes an identity. The substitution is not invalidated by any differences between latitude and motion: write x for latitude and y for calculation, and the argument is unaffected. My question is: What other conclusion is possible? It is not a mathematical question: a mathematical answer is simply a sign that the point has been missed. Only a sentence is needed, and no correspondent gives that sentence.

Even a brief reflexion on the consequences of a disproof of the special relativity theory shows how fundamental they are. In the first place, 'space-time', as something having objective significance, is abolished, and 'universal time', independent of space, is restored—not, however, as a necessity of thought as in the old days, but as the only concept of time that makes possible a consistent description of nature. There is no limit to the velocities attainable by material bodies, and—unless there is, in fact, an ether of the Lorentz type which modifies bodies moving through it—there is no contraction of rods, slowing-down of clocks, increase of mass, and so on, accompanying motion.

Electromagnetic theory, on the other hand, needs revision, and three possibilities seem open. First, the *ad hoc* assumptions just mentioned, which were introduced by Lorentz to protect his equations from the assaults of observation, may be again called into service. This, however, would raise the new problem, as difficult as that which it displaces, of finding a reason for such arbitrary changes. Secondly, the converse process to Einstein's might be tried. His theory was devised to reconcile the equations of mechanics with those of the Maxwell–Lorentz electromagnetic theory by changing the independent variables in the former so that the equations obeyed the Lorentz transformation to which the latter were invariant. That having failed, the independent variables of the electromagnetic equations might be regarded as functions of the space and time co-ordinates of Newtonian mechanics, and the functions sought which would render those equations invariant to the Galilean transformation: this would be, in effect, to locate the 'space–time' fiction in electromagnetism instead of in mechanics and ordinary experience. It is a purely mathematical problem to discover whether such functions exist. If not, then the only remaining possibility would seem to be a fundamentally different electromagnetic theory, perhaps on the lines adumbrated by Ritz[2] or those which Faraday outlined and Maxwell mistakenly identified with his own[3], or something directly introducing quantum conceptions. This might seem inadmissible in view of the impressive evidence for the Maxwell–Lorentz theory, but it would be no more remarkable than the supersession of Newton's gravitation theory by Einstein's —which, incidentally, need not share the breakdown of the special relativity theory.

But, whatever may be the right solution, electromagnetic theory is so intimately involved in the whole of sub-atomic physics that the entire subject must be submitted to revision if the special relativity theory is disproved, and the importance of this is so great that a clear settlement of the question, before kinematical velocities not negligible compared with that of light become possible, is imperative. This demands a genuine effort to examine the matter with a completely unprejudiced mind. The general impression which these replies give is that the obstacles to the acceptance of my argument are mainly psychological: my communication has been read, not to see if what I say is right, but to see where it is wrong. If my critics could only manage to conceive the possibility that it might be right, I think they would at once see that it is; it is so very simple.

OBITUARIES

Dr. L. B. Turner

DR. LAURENCE BEDDOME TURNER, who died in a nursing home on January 28, was born at Charlton, Kent, on April 6, 1886. He was among the earliest of the advanced engineers in Great Britain engaged in research on wireless techniques as applied to practical signalling by continuous electromagnetic waves using the thermionic valve.

L. B. Turner was educated at Bedford Grammar School and King's College, Cambridge, obtaining honours in the Mechanical Sciences Tripos in 1907. Following a year's research in the Engineering Laboratory, he was awarded the John Winbolt Prize for an essay on his work. After acquiring practical experience at the works of Messrs. Siemens Brothers, Woolwich, and at Siemens and Halske in Berlin, he entered the Post Office as an assistant staff engineer in 1910. Here he was engaged in experimental work, and in the design of ship and shore stations. During the First World War he was at the Army's Signal Experimental Establishment at Woolwich, where he designed field apparatus, including portable transmitters for short wave-lengths.

At the end of the War he left the Post Office to return to Cambridge as Fellow of King's College and director of studies in engineering. Later he became a technical adviser on the Postmaster-General's Committee concerned with the establishment of a world-wide long-wave wireless chain, of which the Hillmorton Station near Rugby, and that at Abu Zabal near Cairo formed the first link. While the Rugby Station, still in use, has proved to be an outstanding success as a reliable sending station of world-wide range, the principle of the chain as a whole was overtaken by the development of the short-wave beam system by Franklin and Marconi.

L. B. Turner became a corporate member of the Institution of Electrical Engineers in 1920, and was one of the founder members of the Wireless Section of the Institution. He was chairman of the Section for the session 1922–23, and in his inaugural address he gave an excellent review of the development of the thermionic valve during the early years of its application to wireless signalling. As a supplement to the address he gave an interesting account of some original work on spontaneous fluctuations in valve amplifiers. He patented in 1920 a two-valve circuit arrangement designed to amplify weak radio signals at the same time reducing the strength of prevailing atmospheric disturbances.

The remarkable developments in wireless communication during the First World War demanded new works of reference, and L. B. Turner was one of the first in the field with his *Outline of Wireless*, published in 1921. This was followed ten years later (1931) with his more comprehensive volume entitled: *Wireless: a Treatise on the Theory and Practice of High-Frequency Electric Signalling*. Both books were noteworthy for their clarity of description of the fundamental principles of the subject, with an adequate presentation of practical details.

The versatility of Turner's interests was, however, well demonstrated by a paper he read before the Institution of Electrical Engineers in 1937 on the principles of design of electrical thermostats, and containing a description of a mains-operated isothermal chamber constant to one-thousandth of a degree Centigrade.

During the Second World War he was with the Admiralty Signals Establishment at Portsmouth, where his work was excellent if less well known than during the First World War. He returned afterwards to Cambridge, where he was able to devote himself to further research. He was made a University reader in 1948.

R. L. SMITH-ROSE

Mr. A. Warmisham

ARTHUR WARMISHAM, who died on November 10, read mathematics in the University of Manchester under Prof. H. Lamb and Mr. (later Sir) Charles Darwin, and graduated M.Sc. In 1912 he entered the firm of Taylor, Taylor and Hobson (now Rank Taylor Hobson) as optical designer. In those days the number of university men (apart from chemists) entering industry was small—of mathematicians practically none. There was no technical training in optical design apart from a small course for sight-testing opticians at the Northampton Polytechnic (now the Northampton College of Advanced Technology), so that English optical designers (such as H. Dennis Taylor) had to teach themselves. So it was with Warmisham; practically the only books were Dennis Taylor's *System of Applied Optics*, based on Coddington, and von Rohr's *Formation of Images in Optical Instruments*.

With the First World War came the development of aircraft and the use of photography for reconnaissance. It was found that at the aperture (*f*/4·5) and field (35°) most suitable, English photographic lenses were inferior to one German lens (which, of course, was no longer available). It happened that Warmisham had been examining the 4-element type of anastigmat and had developed a lens remarkably free from coma over just this field and at this aperture, and this property was valuable in improving contrast in the image, facilitating the recognition of detail. The lens (and others) was tested by the Royal Flying Corps side-by-side with the German and found to be superior. It was accordingly extensively used in air photography, and appropriately named the *Aviar*.

After the War his task was to adapt the *Aviar* to professional use, and it became very popular. An apochromatic form was designed for process work.

Improved standards of definition were demanded by the cinematograph industry both for taking and projecting lenses. Warmisham designed a remarkable series of projection lenses of greater aperture to give the brighter picture required for the larger cinemas which were then being built. Another demand came with the introduction of talking films. Hitherto, variation in the scale of the image (for 'close-ups', etc.) was made by moving the camera to and fro, with visual focusing. This was objectionable when sound was recorded. All extraneous noises had, of course, to be eliminated. Warmisham visited the United States and there invented a lens of variable focal length. By variation of the separation of the components not only was the focal length changed (and with it the scale of the picture), but the image was kept automatically in focus throughout the range of movements, without shift of the camera. This was not the first 'variable focus' lens but the first to achieve an acceptable standard of definition over a wide range of focal lengths, at high aperture. 'Zoom' lenses, as they are called, are now widely used in cinematography, television and still photography and projection.

Warmisham published little, but he was a prolific inventor, as the files of the Patent Office show—in fact, he invented more than he could develop to marketable form. Many of to-day's well-known optical designers received their early training under his guidance, and the wide use and adaptation of his methods under present-day conditions in Great Britain and overseas is a tribute to his contribution to the art.

'A. W.', as he became known, was no respecter of persons and had a caustic yet humorous way of expressing somewhat candid opinions, but these were given with a Puckish grin that disarmed resentment. H. W. LEE

NEW FELLOWS OF THE ROYAL SOCIETY

At a meeting of the Royal Society on March 21, the following were elected to fellowship of the Society:

Dr. J. B. Adams, director of the Culham Laboratory of the U.K. Atomic Energy Authority, Abingdon, distinguished for his contributions to the design and construction of the 25-GeV proton-synchrotron at the European Centre for Nuclear Research, Geneva.

Sir Eric Ashby, Master of Clare College, Cambridge, distinguished for his outstanding services to the advancement of science and for his contributions to botany.

Prof. H. N. Barber, professor of botany in the University of Tasmania, Hobart, distinguished for his work in experimental cytology, population genetics and the genetics of flowering.

Prof. E. H. S. Burhop, professor of physics in University College, London, and at present at the Accelerator Division, CERN, Geneva, distinguished for his contributions to experimental and theoretical atomic and nuclear physics, particularly to the Auger effect and atomic collision processes.

Prof. H. G. Callan, professor of natural history in the University of St. Andrews, distinguished for his researches in the field of cytogenetics and for his analysis of the synthetic functions of chromosomes.

Dr. J. W. S. Cassels, Caley lecturer in mathematics in the University of Cambridge, distinguished for his contributions to the theory of numbers and in particular to Diophantine approximation and the arithmetic of curves of genus one.

Prof. T. N. George, professor of geology in the University of Glasgow, distinguished for his researches on the stratigraphy and palæontology of the Lower Carboniferous and the application of palæontology to the theory of evolution.

Prof. J. L. Gowans, Henry Dale research professor of the Royal Society, Sir William Dunn School of Pathology, Oxford, distinguished for his elucidation of the life-history and physiological function of the lymphocyte.

Dr. P. B. Hirsch, lecturer in physics in the University of Cambridge, distinguished for his researches with the electron microscope on imperfections in the crystalline structure of metals and on the relation between structure defects and mechanical properties.

Dr. J. H. Humphrey, head of the Division of Immunology in the National Institute for Medical Research, London, and deputy director of the Institute, distinguished for his immunological researches, in particular on the synthesis of antibody and the mechanisms of hypersensitivity.

Prof. P. L. Krohn, professor of endocrinology in the University of Birmingham, Department of Anatomy, distinguished for his researches on the transplantation of endocrine glands, particularly in its bearing on the ageing process.

Dr. D. Küchemann, deputy chief scientific officer, Royal Aircraft Establishment, Farnborough, distinguished for his theoretical and experimental work in aerodynamics, particularly in studies of wing-forms for supersonic flight.

Dr. M. S. Longuet-Higgins, senior principal scientific officer, National Institute of Oceanography, Wormley, Surrey, distinguished for his contributions to physical oceanography and especially for his investigations into ocean waves.

Dr. J. F. Loutit, director, Radiobiological Research Unit, Medical Research Council, Harwell, distinguished for his work in radiobiology, and particularly for his interpretation of recovery from radiation injury.

Dr. J. W. G. Lund, senior principal scientific officer, Freshwater Biological Association, Ambleside, Westmorland, distinguished for his work on freshwater biology, particularly on the taxonomy and ecology of algae.

Dr. Sheina MacAlister Marshall, principal scientific officer, Scottish Marine Biological Association, Marine Station, Millport, Isle of Cumbrae, distinguished for her researches on the productivity of the sea and on the bionomics of marine planktonic organisms.

Prof. P. T. Matthews, professor of theoretical physics in the Imperial College of Science and Technology, London, distinguished for his contributions to quantum field theory and the theory of elementary particles.

Dr. B. Y. Mills, senior principal research officer, Division of Radiophysics, Commonwealth Scientific and Industrial Research Organization, Sydney, Australia, distinguished for his contributions to radio astronomy and especially for the development of a novel form of high-resolution radio telescope.

Dr. C. G. Phillips, Fellow of Trinity College and reader in neurophysiology in the University of Oxford, distinguished for his work on the physiology of the central nervous system, in particular on the control of muscular movement.

Dr. J. A. F. Roberts, director, Clinical Genetics Research Unit, Medical Research Council, Hospital for Sick Children, London, W.C.1, distinguished for his researches into human heredity, particularly in relation to mental ability.

Dr. L. Rotherham, Board member for Research and Development, Central Electricity Generating Board, London, distinguished for his work on the manufacture of new metals and for his contributions to research associated with the development of the generation of nuclear power.

Dr. T. S. Stevens, reader in organic chemistry in the University of Sheffield, distinguished for his original researches in organic chemistry, particularly for his work on the mechanism of molecular rearrangements.

Dr. T. M. Sugden, reader in physical chemistry in the University of Cambridge, distinguished for his work on the detection and identification of transient species, radicals, ions and electrons, in flames and on the reaction mechanisms involved.

Dr. D. Tabor, lecturer in physics in the University of Cambridge and deputy director of the Research Laboratory for the Physics and Chemistry of Solids, Cavendish Laboratory. Distinguished for his original work on the physical and mechanical properties of solids.

Prof. A. J. C. Wilson, professor of physics in the University College of South Wales and Monmouthshire, Cardiff, distinguished for his contributions to X-ray analysis in the elucidation of the atomic structure of crystals.

NEWS and VIEWS

Royal Society Research Professorship: Prof. G. H. Beale, M.B.E., F.R.S.

THE first of the Royal Society research professorships, for which the Government made provision in 1962, has been awarded to Dr. G. H. Beale, of the Department of Genetics, University of Edinburgh. G. H. Beale was born in London in 1913, and graduated in botany at the Imperial College of Science and Technology in 1935. From then until 1940 he worked on flower pigments at the John Innes Horticultural Garden, being one of the group of workers who, under the inspiration of J. B. S. Haldane, made the first successful attempt to describe gene effects in biochemical terms. During the Second World War he served in the Army, spending two years in northern U.S.S.R. and another two in Finland. During 1946–47 he worked on bacterial genetics in Demerec's laboratory in Cold Spring Harbor, Long Island, and then moved to Indiana with a Rockefeller fellowship to study the genetics of *Paramecium* with Sonneborn. He returned to Great Britain in 1948, and joined the Institute of Animal Genetics at Edinburgh, where he has remained ever since, first as a lecturer and later as reader in the University Department of Genetics. He was elected a Fellow of the Royal Society in 1959.

Since his return to Britain, Prof. Beale has devoted his attention to *Paramecium* and in particular to the complex and revealing interplay between cytoplasmic factors and nuclear genes in controlling the appearance of antigenic substances. By the time his monograph on *The Genetics of Paramecium aurelia* appeared in 1954, he had already shown that the antigens are controlled by several gene loci, at each of which a number of alleles exist, and that it is some condition or 'state' of the cytoplasm that decides which of the gene-loci shall be active and bring about the appearance of its characteristic antigen. This is a system of the greatest theoretical importance, since it is exactly of the kind that has often been postulated to explain the processes of embryonic development, but has the advantage of being much more accessible to analysis, both genetical and biochemical, than any known embryonic system. In recent years considerable progress has been made in characterizing the chemical nature of the antigens; they are proteins, of rather high molecular weight, but quite accessible to detailed study. The nature of the cytoplasmic 'states' is more obscure; but Beale and his associates have recently discovered a quite unexpected type of cytoplasmic entity, namely particulate elements, which they name 'metagons', capable of persistence but not of multiplication in the absence of a corresponding gene, and involved in the maintenance of the symbiotic 'killer' particles which may inhabit the cytoplasm of *Paramecium*.

Pure Mathematics at Monash: Prof. G. B. Preston

PROF. G. B. PRESTON, associate professor of mathematics at the Royal Military College of Science, Shrivenham, has been appointed to the foundation chair of pure mathematics at Monash University. He was formerly a mathematical scholar of Magdalen College, Oxford, and has held an appointment at the Royal Military College of Science since 1949. During 1956–58 he was a visiting assistant professor at Tulane University, New Orleans, where he collaborated with Prof. A. H. Clifford on a monograph on the algebraic theory of semigroups. He was promoted to associate professor at Shrivenham in 1961 under the scheme whereby scientists in the Civil Service are rewarded for research work of special merit.

Scientists in Government Services

IN a written answer in the House of Commons on March 12 to a question regarding action on the recommendations of the Zuckerman report regarding transfer of research staff and interchange between posts in the Scientific Officer Class and in other Civil Service classes, the Financial Secretary to the Treasury, Mr. A. Barber, stated that these recommendations had been fully considered in the Interdepartmental Panel. There were already more than 500 posts in the scientific-officer class established at headquarters of the departments for scientific and general administration, and the use of scientists on this type of work was being extended. While the Committee's recommendations were unacceptable, experience provided little evidence that any significant number of scientists employed in the Civil Service who had a marked capacity for administrative work wished to be employed in this way.

The Parliamentary and Scientific Committee

THE annual report of the Parliamentary and Scientific Committee for 1962 records that the Sub-Committee, confined to Parliamentary members, set up to consider the future of research associations, reported in July, and the report has been submitted to the Minister for Science (Pp. 22. London: Parliamentary and Scientific Committee, 1963). It is hoped that the issues raised may be discussed by representatives of the Committee with the Minister in due course. Discussions and talks during the year covered the Gibb–Zuckerman report; the future of water supplies, water conservation, etc., in Great Britain; technical considerations relating to the Channel tunnel and Channel bridge; problems of diseases arising out of the use of new materials and processes in industry and agriculture; nuclear energy in Great Britain; Soviet science; and recent developments in connexion with mechanical engineering research in Great Britain.

The Microchemical Journal

THE Academic Press will continue to publish *The Microchemical Journal*, under the auspices of the American Microchemical Society (formerly Metropolitan Microchemical Society). The first six volumes were published by Interscience Publishers. The new editor-in-chief is Dr. Al Steyermark, of Hoffmann-La Roche, Inc., Nutley, New Jersey. He is assisted by four editors: H. A. Flaschka, Howard J. Francis, jun., Keiichiro Hozumi and Wolfgang J. Kirsten, and an advisory board. Starting with Vol. 7, 1963, the *Journal* will cover a broader field. Research articles of all phases of chemistry involving small-scale manipulation are eligible for consideration. Manuscripts dealing with both organic and inorganic work relating to the preparation, purification, separation, detection, determination, trace analyses, clinical chemistry, and all types of instrumentation—microscopy, chromatography (thin-layer, paper, gas), spectroscopy (infra-red, ultra-violet, mass, X-ray), nuclear magnetic resonance, and neutron activation, may be submitted to the editor-in-chief. During 1963, four issues will be published. The price for Volume 7 is 16.00 dollars. Further information can be obtained from the Academic Press, 111 Fifth Avenue, New York 3, or Academic Press, Berkeley Square House, London, W.1.

The British Museum (Natural History)

THE British Museum (Natural History) has recently issued the tenth edition of its short *Guide to the Exhibition Galleries* (Pp. vi + 38. London: British Museum (Natural

History), 1963). In general format and contents this is similar to the previous edition of 1962, and the difference is mainly due to four additional pages of text and two extra illustrations. This is chiefly an account of the recently opened botanical gallery and illustrations of their dioramas and wall cases. It is unfortunate that one illustration scarcely does credit to the attractive mineral barytes.

The Durban Museum and Art Gallery

The report for 1961–62 of the Durban Museum and Art Gallery records the completion of the new Hall of Marine Life and the start of five new displays in the entrance hall (Pp. 24. Durban: Durban Museum and Art Gallery, 1963). An illustrated guide to the three major modernized galleries has been issued and several collecting expeditions have been made by the staff. The list of papers published is an impressive one considering the size of the staff.

Department of Scientific and Industrial Research Grants, 1963

D.S.I.R. Research Grants, 1963, summarizes information regarding the Grants for Special Researches awarded by the Department of Scientific and Industrial Research (Pp. vi+9. London: H.M.S.O., 1963. 1*s*. 6*d*. net). These grants are given to supplement resources derived from the University Grants Committee or elsewhere and are not intended to meet the entire cost of research projects or to replace existing resources. The awards are for investigators who are already of acknowledged standing in their subjects. Grants may be given for the support of researches in astronomy, biology, chemistry, geology, mathematics, physics and the sciences between and adjoining these, and also in applied science and technology, and engineering; but applications for assistance in subjects in which the Agricultural Research Council, the Development Commission, the Medical Research Council or the Nature Conservancy are directly interested should be made to the appropriate body. Applications for grants in certain branches of the humanities and social sciences may also be considered where appropriate. Notes on Nato research grants and on senior visiting fellowships of the Organization for Economic Co-operation and Development are included.

Gordon Research Conferences, 1963

The Gordon Research Conferences, the purpose of which is to stimulate research in universities, research foundations and industrial laboratories by fostering the exchange of ideas and information, are to be held this year in four research schools in New Hampshire during the period June 10–August 30. Forty-eight informal conferences, each lasting five days, will be held, their subjects covering a wide range of topics in the physical and biological sciences. Residence and registration charges for each conference amount to 100 dollars. Applications should be addressed to, and further information can be obtained from, W. George Parks, director, Gordon Research Conference, University of Rhode Island, Kingston, Rhode Island.

"Notions of Niche and Competition Among Animals, with Special Reference to Freshwater Fish"

Dr. A. H. Weatherley, of the Department of Zoology, School of General Studies, Australian National University, Canberra, has written to the Editor stating that in his article under the above title, appearing on p. 14 of the January 5 issue of *Nature*, he erroneously attributed a definition of competition among animals by Dr. Alec Milne, Agricultural Research Council Unit of Insect Physiology, to Prof. J. L. Harper, University College of North Wales. Dr. Weatherley wishes to apologize for this error to both Prof. Harper and Dr. Milne.

University News:

Bristol

The following appointments to lectureships have been announced: B. M. Bird (electrical engineering); Dr. A. Keller (physics); Dr. R. H. Ottewill (physical chemistry within the Department of Physical and Inorganic Chemistry).

London

The following titles have been conferred: professor of the archæology of the Roman Provinces, on Mr. S. S. Frere, in respect of his post at the Institute of Archæology; professor of hæmatology on Dr. P. L. Mollison, in respect of his post at St. Mary's Hospital Medical School; reader in pharmacology, on Dr. J. R. Hodges, in respect of his post at the Royal Free Hospital School of Medicine; reader in biophysics, on Dr. R. Miledi, in respect of his post at University College; reader in physiology, on Dr. Patricia P. Scott, in respect of her post at the Royal Free Hospital School of Medicine; reader in human nutrition, on Dr. G. R. Wadsworth, in respect of his post at Queen Elizabeth College.

Monash

Prof. M. G. Marwick has been appointed to the foundation chair of anthropology and sociology in the University. Prof. Marwick is at present professor of social anthropology and head of the Department of Social Anthropology and African Administration in the University of the Witwatersrand. During 1962 he was Simon Senior Research Fellow in the University of Manchester.

Announcements

From January 1963, the Council of Scientific and Industrial Research, New Delhi, is issuing research communications in a series of four periodicals: *Indian Journal of Pure and Applied Physics*; *Indian Journal of Chemistry*; *Indian Journal of Technology*; and the *Indian Journal of Experimental Biology*. The *Journal of Scientific and Industrial Research* will continue with all the features included up to December 1962 in its Section *A*.

The Low Temperature Research Station, Cambridge, will hold open days during May 22–23, at which recent and current work will be displayed. Further information can be obtained from the Director, Low Temperature Research Station, Downing Street, Cambridge.

A Symposium on "Moulds for Reinforced Plastics", arranged by the Plastics Institute Reinforced Plastics Group, will be held in London on May 28. Further information can be obtained from J. N. Ratcliffe, Plastics Institute, 6 Mandeville Place, London, W.1.

The annual conference of the Ergonomics Research Society will be held at the College of Aeronautics, Cranfield, during April 1–4. Subjects under discussion will include: process control; workplace layout; machine tools; engineering production; the comprehension of engineering drawings; the effects of heat; the teaching of ergonomics; the future of ergonomics; criteria in ergonomics; the elderly worker in industry. Further information can be obtained from Mr. David Whitfield, Ergonomics Laboratory, College of Aeronautics, Cranfield, Bletchley, Bucks.

A symposium on "The Colorimetry of Near Whites", organized by the Colour Group (Great Britain), will be held at the Imperial College of Science and Technology on April 3. The programme will include: the measurement of whiteness; the scan-test reference instrument for reflectometry; the colorimetry of fluorescent whites; light sources for matching near whites. There will also be an exhibition of colorimeters, spectrophotometers, light sources, colour atlases, colour filters, colour vision tests and allied equipment. The group's first Newton Lecture entitled "The Rays are not Coloured" will be delivered by Prof. W. D. Wright. Further information can be obtained from F. J. B. Wall, Physics Research Laboratory, Ilford Ltd., Woodman Road, Brentwood, Essex.

THE BRITISH BROADCASTING CORPORATION

ANNUAL REPORT

THE annual report for 1961–62 of the British Broadcasting Corporation* welcomes the recent White Paper, *Broadcasting: Memorandum on the Report of the Committee on Broadcasting*†, in so far as it affects the B.B.C., while noting that the Government accepts responsibility to see that the Corporation secures sufficient income to carry out its additional tasks. With the report are published the accounts for the year ended March 31, 1962, showing an income from licence revenue of £36·7 million, expenditure of £13·55 million on operating the sound service, and £20·2 million on the television service, with a grant-in-aid totalling £7·38 million for the External Services.

Immediate steps were taken towards bringing into operation at the earliest possible date the Government's proposals for more hours of sound broadcasting, a second television programme (see following article), a start to colour television, more Welsh and Scottish television and more educational programmes for adults on the present television service. The growth of external broadcasting is particularly stressed, and over the past ten years the combined output of the twelve major countries broadcasting to external audiences has more than doubled, although in the same period the output of the Corporation has declined. The field is now led by the U.S.S.R., the Soviet satellite countries, the Voice of America and Communist China—the last mentioned displacing Britain from the fourth position in 1962. Much of the increased output is directed towards the Asian countries, those of Latin America and the emergent countries of Africa. For this reason, the Corporation warmly welcomes the Government's approval early in 1962 of a major programme of relay-transmitter building which will increase the range and effectiveness of some of the Corporation's transmissions overseas. Some services elsewhere, however, were cut, and the closing down of operations in the United States is particularly regretted. The Governors record their conviction that it is in the national interest that these external services should be maintained over a broad front. Reference is again made to selective jamming of the Corporation's Russian service and to deliberate full-scale jamming of the Hungarian, Rumanian, Bulgarian, Kuoyu and Cantonese services.

Commenting on sound programmes, the report notes the success which attended the concentration into brief space of a series of broadcasts on the Third Programme: for example, a series of scientific broadcasts on "Quanta and Reality" were repeated in a single evening, and five talks and a discussion entitled "Strategy of Survival" were concentrated into two evenings in one week. Much of the year was occupied with preparations for the first trans-Atlantic programme exchanges in association with the Post Office, other European broadcasting organizations and the sponsors of the American communications satellites. The Corporation was also engaged in extensive research into the potential of local broadcasting in Britain. The direct contribution to further education was mainly through broadcasts on Network Three, designed to meet the needs and interests of various minority groups; a new Saturday morning television series, "Science on Saturday", introduced in the summer of 1961, was a first step towards meeting the needs of those wishing to use television for the planned study of science by adults.

Reception in many parts of the United-Kingdom continued to be unsatisfactory because of interference from foreign stations, and although certain technical measures taken improved matters to some extent, with the present overcrowding of the medium wave-band there is nothing further that the Corporation can do to reduce the effect of the interference. The Corporation continued to develop its very-high-frequency services, which are virtually free from interference, and it is estimated that about 4·6 million very-high-frequency receivers are now in use. Much was done during the year to achieve greater reliability and precision in the performance of broadcasting apparatus, and transistor and printed circuit techniques promise great increased reliability and possibly considerable savings in maintenance. Preparations were made for the new series of experimental 625-line transmissions on the very-high-frequency Bands IV and V, including both black-and-white and colour television to begin in the autumn of 1962, and attention has also been turned to the propagation of ultra-high-frequency signals over the sea. With a change in the pattern of engineering recruitment, arising from an increasing demand for engineers in proportion to technical assistants, the Corporation has been less able to meet its full need of engineers by internal promotion. Besides a higher recruitment of qualified men, the Corporation has stepped up its scheme of sandwich courses, but the training facilities have been much more heavily loaded in consequence. Staff at March 31, 1962, numbered 17,125 full-time and 887 part-time, compared with 16,375 and 1,140 in 1960–61.

SECOND TELEVISION PROGRAMME

The opportunities in planning the British Broadcasting Corporation's second television programme are outlined in extracts from an address given at the University of Leeds by Mr. K. Adam, director of B.B.C. Television, and now published in the *B.B.C. Record* (No. 15; November 1962). The second programme is expected to start in April 1964 on 625 lines in very-high-frequency from Crystal Palace and to have reached the North of England by the summer of 1965. It is proposed to begin with at least 25 h of fresh material per week, concentrating on the peak hours each evening with extra hours at the week-end, and in any one evening to cater in depth for a special section of the total audience by, for example, a long play, a feature film, a full-length broadcast of sport, edited versions at length of political and scientific conferences or open-ended discussions. It is uncertain what transmission standards of colours will be used, and Mr. Adam pointed out that colour will always be very expensive and may never average more than one or two hours a night. It is hoped to recruit new writers and to encourage new styles of writing, and Mr. Adam also referred to the possible organization of programmes in collaboration with universities and learned societies.

Science must have its full place in this second programme, and a working group has been set up which will be visiting all regional headquarters to ensure that regional studios are used to their maximum capacity in 1964. In *B.B.C. Record* (No. 16; January 1963) further details are given of production plans which contemplate at least three more London production studios by April 1964, with a fourth to permit expansion to 30 h. Colour transmissions will start before the end of 1964 and the first major production studio at the Television Centre equipped for colour should come into operation in the autumn of 1965. Two-thirds of the population should be receiving the new programme in 1966. The Liaison Committee set up, with Mr. J. S. Fulton as chairman, to guide the Corporation in providing adult education programmes was to hold its first meeting on January 30.

---

* The British Broadcasting Corporation. Annual Report and Accounts for the year 1961–62. (Cmnd. 1839.) Pp. 166+16 photographs. (London. H.M.S.O., 1962.) 10s. net.

† *Broadcasting: Memorandum on the Report of the Committee on Broadcasting*, 1960. Pp. 12. (Cmnd. 1770.) (London. H.M.S.O., 1962.) 1s. 3d. net. [See also *Nature*, 195, 927, 1962.)

In the first of a series of lunch-time lectures at Broadcasting House, published as *B.B.C. Lunch-time Lectures—I*, Mr. L. Miall discussed the future of B.B.C. Television after explaining why a new service must be started in what are, for the Corporation, quite new and more difficult broadcasting bands—the very-short- or the ultra-high-frequency bands known as *IV* and *V*. These bands will involve, in effect, new sets for viewers but will give much more space to accommodate new programmes. Mr. Miall emphasized that the process of changing over and building new transmitters, which will gradually carry the Corporation to all parts of the country, is a huge engineering task, involving a capital cost likely to exceed £40 million and building and operating more than 250 new transmitters as well as many low-powered booster transmitters. Co-siting with the Independent Television Authority is essential if the amenities of the countryside are not to be damaged excessively. In indicating some of the plans for new programmes, Mr. Miall concluded by stressing the necessity of avoiding any debasement of the medium.

Lecture 2 dealt with B.B.C. news and current affairs, and, after claiming that the Corporation endeavours to achieve a balance between what the public wants and what the maturer members of the public needed, Mr. D. Edwards forecast great developments in relation to science, which more and more provides news. The Corporation hopes to help the increasing number of scientists, and, besides building up the number of its science producers, he thought that the Corporation would provide in its second television programme a regular programme, doing for science what "Monitor" has done for the Arts. A third lecture, by M. Pulling, on "International Television" pointed out that viewers in Britain saw less of *Eurovision* than viewers in many other European countries. However, while the complete elimination of the 405-line standard in Britain and the 819-line system in France would take many years, an important improvement would result both in the quality of pictures from other countries seen in Britain and in those from Britain seen in other countries: benefit would begin with the start of the second television programme. Finally, the facilities offered by a successful satellite communications system seemed sufficiently attractive to justify the immense efforts required.

THE LEVERHULME TRUST

THE fourth report of the Leverhulme Trust covers the years 1959–61, in which grants and awards totalling £885,000 were committed as compared with £593,000 during the previous triennium[*]. While the expansion is due to a widening of the field of interest of the Trustees, the general policy remains one of initiating new ventures, and neither capital grants for buildings or equipment nor general appeals are considered.

The primary concern is still fellowships and scholarships, and, of the total, 42 per cent has gone to universities and other forms of higher learning and 21 per cent to medical research. Of the £371,150 for universities, £104,400 was for overseas visiting fellowships and £50,000 for fellowships in general research at the University of Liverpool. £6,600 went to the Department of Animal Husbandry and Veterinary Surgery at the University of Bristol for research into digestibility and into anaesthesia in domestic animals; £5,100 for biochemical research on the cell nucleus at the University of Edinburgh; £13,500 to the University of Hull for research fellowships on Commonwealth studies; £12,950 to the London School of Economics for scholarships and research awards; £15,000 to the Institute of Education, University of London, for an advanced training course concerned with the use of mass media, and £3,300 to the Institute's Research Unit for Student Problems. The University College of South Wales and Monmouthshire received £10,000 for business administration fellowships, the University College of Swansea £9,000 for research scholarships in social science, the University of Manchester £4,400 for an extension of research fellowships and studentships at Jodrell Bank Experimental Station, and £11,600 was provided for overseas visiting fellowships for the Manchester and Glasgow Colleges of Science and Technology. Besides £31,500 for a professorship in geology at the University of the Punjab, £9,000 went to the Kenya College of Social Studies for the salaries of two tutors, and £5,000 for overseas visiting fellowships for the universities of Holland.

Awards totalling £46,550 to learned societies and research institutions include £2,000 to the Acton Society for its inquiry into the role of the arts graduates in industry; £6,000 to the British Association for research on the Lowenfeld–Dienes method of teaching mathematics; and £19,900 to Political and Economic Planning for its study of trade unions in a changing society and £4,100 for its study of international government. The Institute of Community Studies received £4,000 towards various research projects which include various studies in depth of the experience of students at Cambridge, Manchester and Southampton of factors determining the choice of specialization, the compatibility of effective vocational training with a broader intellectual education, comparative quality of different methods of teaching, the effect of halls of residence, living in college, and unions and societies on vitality of the university and relations between staff and students, and the Institute of Strategic Studies £3,250 for the salary of a research assistant.

Of the awards totalling £184,900 for medical research, £90,000 was to the African Research Foundation in East Africa for cancer research, £28,000 to the East Grinstead Research Trust for a research fellowship and laboratory assistants, and £3,900 to the Department of Education of the Deaf, University of Manchester, for research on hearing aids for children. Grants for research fellowships included £5,150 to the Institute of Dental Surgery, £6,000 to St. Mary's Hospital Medical School, and £6,900 for a surgical research fellowship at Guy's Hospital. The Royal College of Surgeons received £12,000 for continuation of a research fellowship in the Faculty of Anaesthetists, and £6,000 for continuation of one in the Department of Physiology; the Institute of Laryngology and Otology £4,050 to extend research on the physiology of hearing and balance into the central nuclei and tracks in the brain, and University College Hospital Medical School £5,000 for the interchange of students between London and Ibadan. Various other grants were to the London School of Hygiene and Tropical Medicine, including £9,000 for secondment to Makerere College, Uganda, £3,000 to the Ross Institute, and £2,500 to the Human Nutrition Research Unit.

Besides awards of £3,000 for archaeology, miscellaneous grants included £12,000 to the Commonwealth Society for the Deaf for training African students as teachers of the deaf, £15,000 to the Royal Commonwealth Society for Voluntary Services Overseas, £7,500 to the Educational Interchange Council for Research Scholarships, and £32,500 to the National Bureau for Co-operation in Child Care.

IMPERIAL COLLEGE SIERRA LEONE EXPEDITION 1963

THIS summer, Imperial College of Science and Technology is sending an expedition of undergraduate biologists to Sierra Leone. The main purpose of the expedition is to carry out a comprehensive study of the flora and fauna of the Northern Province. It is hoped to direct particular attention to the Scarcies River basin and, if possible, to the Loma Mountains. This will be the third expedition from the College to Africa in two years, others being to Nigeria and Ethiopia. The expedition is being made up of five botanists and three zoologists. Two members have had previous expedition experience and all the botanists have worked on the vegetation of the montane region of southern Yugoslavia. An extensive programme of collection and observation is being worked out. It is hoped to bring back several thousand specimens: these will be deposited either at the Kew Herbarium, the Commonwealth Mycological Institute, or the British Museum (Natural History).

In addition to the general survey, the expedition is undertaking work on behalf of the Food and Agriculture Organization. In particular, a survey will be made of indigenous food plants, and it is hoped to collect wild coffee plants of possible value for future taxonomic or breeding work. The zoologists will be primarily concerned in making observations and collections of the fauna of the area, and in particular on the Heteroptera and Coleoptera. A collection of Mollusca will be made to continue work by the Nigerian Expedition on the Mollusca of West Africa. Collections of mammal and bird parasites will also be made, and blood smears taken for pharmaceutical purposes.

The expedition will spend approximately eight weeks in Sierra Leone, and a full report will be published. If the aims of the expedition are accomplished then further expeditions may well continue the work in future years.

P. ROGERS

TROPICAL PARASITOLOGY

THIS symposium, the first regional symposium of its kind, was organized jointly by the Unesco South-east Asia Science Co-operation Office and the Department of Parasitology, University of Singapore. It was held at the Medical School, University of Singapore, during November 5–9, 1962. It was convened under the chairmanship of Prof. R. S. Desowitz. The purpose of the symposium was to provide an opportunity for an exchange of experiences and results among research workers in the field of tropical parasitology.

The conference was attended by delegates from Australia, Ceylon, Hong Kong, India, Indonesia, Japan, Malaya, the Philippines, Singapore, Taiwan, Thailand and Vietnam. These delegates, as well as representatives from the World Health Organization and the Food and Agriculture Organization, had been invited by Unesco to attend the conference. Dr. N. Ansari, chief of Parasitic Diseases Branch, represented the World Health Organization.

The symposium opened with an address of welcome by the vice-chancellor of the University of Singapore, Dr. B. R. Sreenivasan. This was followed by an introductory address by Mr. L. Matteson, director of the South-east Asia Science Co-operation Office, Djakarta.

The first day was taken up by a series of survey papers relating to the background and progress of work in the field of parasitology in the various countries included in the region. An interesting feature of these reports was their refreshing variety of approach. Each report, in its different way, described the background of endeavour which had resulted in the establishment of the various institutions where parasitology is studied throughout the South-east Asian region and gave details of the investigations which were being carried on. These reports constituted a valuable contribution and comprise not only a useful compilation pertaining to the history of parasitology in this region but also an index of personnel, institutions, and bibliographies.

Although the scope of these reports was by no means uniform, it was nevertheless a prominent feature that they emphasized the need for further co-operation and interchange of ideas among parasitologists in the South-east Asian region.

It was evident that there has been a marked improvement in the overall facilities available for research on parasitic diseases in the tropics. Places which were once little more than field stations have now become centres of basic parasitological research. The important implication of this is that the most up-to-date laboratory apparatus is now within relatively easy access to the front line of research in the parasitological field, so that direct investigations on the important disease-producing parasites can be conducted. Previously, it had so often occurred that the basic observations on morphology, physiology, immunology, etc., were restricted to parasites which could be maintained in the laboratory.

On the other hand, it was also evident that the old problems of disease and untimely death are still the main concern of parasitologists over most of the South-east Asian region. But the vigorous research programmes relating to the diagnosis and control of parasitic diseases now operating in many of the South-east Asian countries, coupled with the frequent visits being made by specialists in various fields, and the close liaison which has evidently been established with universities and research centres in other parts of the world, gives promise of a successful campaign against the protozoa, worms and arthropods which still cause such widespread disease in tropical regions.

This overall emphasis on medical parasitology is in contrast with the situation in Australia, where the parasites of domestic animals appear to comprise the most important application of parasitology, and where it is evident that funds for research in the field of veterinary parasitology far exceed those available for medical parasitology.

Three full days were devoted to research papers; these again showed a remarkable diversity of interest. Thus, there were papers of a clinical nature, some dealing with lesions and symptoms, others with method of control, epidemiology, and treatment. But there were also papers devoted to the basic principles of parasitology, such as the immunology of parasitic infections, the physiology and metabolism of parasites, as well as systematics, ecology, evolution, and phylogeny in relation to parasitic organisms.

The whole symposium achieved a balance of emphasis between, on one hand, the fundamentals of structure and function in relation to parasitism, and, on the other, the distress and hardship which parasitism involves.

It is not intended to summarize the content of these individual papers, because it has been arranged that a full report of the proceedings of the symposium will be published. Suffice it to say that the admixture of hypothesis, observation and application contributed to no small extent to the feeling which prevailed that we were all, in spite of widely differing specializations, primarily parasitologists.

The delegates were accommodated in the King Edward VII Hall of the University of Singapore near the Medical School. This contributed in a special way to the success of the symposium. Scientific meetings are becoming more and more intensive, consequently programmes are sometimes so full that there is virtually no time for discussion. This means that the younger delegates have little or no opportunity for discussion of their problems with their more experienced colleagues, who are quite understandably occupied with exchanging greetings with their old friends. This symposium showed the value of delegates living in the same residence and sharing the same table at meals. Ample opportunities were thereby available for discussion, and as a result, one really felt that this had been a conference in the true sense, because all delegates had had an opportunity to become acquainted. In this way many new friendships were made, and much valuable information was imparted between the meetings.

The last day was devoted to a discussion on future policy in relation to co-operation and interchange between parasitologists in the South-east Asian region. Several recommendations were made which, it is hoped, will help to formulate a policy which will ensure further meetings of this kind and possibly the formulation of a permanent panel for the region.

Delegates unanimously resolved to record their sincere appreciation of the services rendered to international science in the field of parasitology to Unesco coupled with the name of its regional representative, Mr. L. Matteson, and to the host country, Singapore, coupled with the name of Prof. R. S. Desowitz, for the excellent arrangements which had been made. All agreed that the conference had been an unqualified success.

J. F. A. SPRENT

COSMIC NUMBERS

By E. R. HARRISON

Rutherford High Energy Laboratory, Chilton, Didcot, Berkshire

IT has been suggested many times (perhaps first by Weyl[1]) that there might be a close connexion between the separate domains of atomic or nuclear physics and cosmology. This view is admittedly intuitional and the only evidence in support of it so far comes from the numerical coincidences of large dimensionless 'cosmic numbers'. The most typical of these numbers are[2]:

$$\frac{R}{a_0} \simeq \frac{cT}{e^2/m_e c^2} \simeq 4 \times 10^{40} \tag{1}$$

$$F_1 = \frac{e^2}{G m_p m_e} = 0{\cdot}3 \times 10^{40} \tag{2}$$

In (1) the characteristic radius of the universe $R \simeq cT$ is expressed in terms of the classical electron radius $a_0 = e^2/m_e c^2$, where T^{-1} is Hubble's constant and $T \simeq 1{\cdot}3 \times 10^{10}$ light years is a characteristic age of the universe. The result is similar if the pion Compton wave-length (indicating the range of the nuclear forces) is used instead of the classical electron radius. In (2) the 'force ratio' F_1 is the ratio of the Coulomb and gravitational forces between an electron and proton. In (1) and (2) e is the charge, m_p and m_e are the masses, G is the gravitational constant, and c is the velocity of light. If g is the pion–nucleon coupling constant[3] ($g^2/\hbar c \simeq 15$) the ratio of the strong interaction between two nucleons, separated by a distance of approximately a_0, and their gravitational force is:

$$F_1 \simeq \frac{g^2}{G m_p^2} \simeq 0{\cdot}3 \times 10^{40} \tag{2'}$$

and this is an alternative expression for the force ratio F_1. If numbers such as $\alpha = e^2/\hbar c = 1/137$, $g^2/\hbar c \simeq 15$, and $m_p/m_e = 1{,}836$, are regarded as occupying a level of order unity, then we can write:

$$\frac{R}{a_0} \sim F_1 \tag{3}$$

It is possible to construct a range of cosmic numbers, and one of their fascinations is their hierarchical structure. This is shown by the following examples. The gravitational radius of the universe is R, and in the case of a nucleon the gravitational radius is $a_g \simeq G m_p/c^2$ (a nucleon of radius a_g produces curvature in the metric of equal radius), and therefore:

$$\frac{a_g}{a_0} \simeq \frac{G m_p m_e}{e^2} = F_1^{-1} \tag{4}$$

The actual or observable mass of the universe is $M \simeq Rc^2/G$, and its density ρ in terms of the nucleon density $\rho_0 \simeq m_p/a_0^3$ is

$$\frac{\rho}{\rho_0} \simeq \frac{M}{m_p}\left(\frac{a_0}{R}\right)^3 \simeq F_1\left(\frac{a_0}{R}\right)^2 \sim F_1^{-1} \tag{5}$$

Expressing M in nucleon masses we obtain Eddington's number $N = M/m_p$:

$$N = \frac{M}{m_p} \simeq \frac{Rc^2}{G m_p} = F_1 \frac{R}{a_0} \sim F_1^2 \tag{6}$$

and similarly, $R/a_g \simeq F_1^2$.

The numbers considered so far are of the form F_1^n, where n is either a positive or negative integer or zero The cosmic numbers, however, are not limited to only integral values of n. Thus, if a mass has as a radius R_s equal to its gravitional radius $2GM_s/c^2$, and a density $\rho_0 \simeq m_p/a_0^3$ equal to that of nuclear matter, the number of nucleons in the mass is $N_s = M_s/m_p$, or:

$$N_s \simeq (\tfrac{1}{2} F_1)^{3/2} \sim F_1^{3/2} \tag{7}$$

which is close to the number of nucleons in a massive star[4]. It is seen that a star at nuclear density has a radius given by:

$$\frac{R_s}{a_0} \simeq N_s^{1/3} \sim F_1^{1/2}, \quad \frac{R_s}{R} \sim F_1^{-1/2} \tag{8}$$

and is the geometric mean of the radii of a nucleon and the universe. Furthermore, if we use the natural length $\lambda = (\hbar G/c^3)^{1/2}$ for quantum fluctuations of the space-time metric[5], then:

$$\frac{\lambda}{a_0} = \left(F_1 \alpha \frac{m_p}{m_e}\right)^{-1/2} \sim F_1^{-1/2} \tag{9}$$

Using this result further numbers can be constructed. (The mass density of the fluctuations is F_1^2 times that of a nucleon; each cell of volume λ^3 has a mass of $F_1^{1/2}$ nucleons, and there are $F_1^{3/2}$ cells per nucleon.)

There is thus a second group of dimensionless numbers of the form F_1^n where n now has half-integral values. The two groups together form a hierarchy of numbers arranged at the discrete levels of the order F_1^n, where $n = 0$,

$\pm \tfrac{1}{2}, \pm 1, \pm \tfrac{3}{2} \ldots$ Whether there is a third group of quarter-integral values of n of any significance is a matter for speculation (for example, the number of stars per galaxy and the number of galaxies in the Universe is of the order $F_1^{1/4}$) and at the present stage of our knowledge the subject scarcely seems worth pursuing. The apparent coincidence of the numerical values of R/a_0 and F_1 has in the past been a reason for suggesting that the physics of the atom and the cosmos are in some way linked together. The hierarchy of numbers such as (1)–(9) with its simple and well-defined relationship gives further support to this point of view. According to Dirac's principle[6]: "any two of the very large dimensionless numbers occurring in Nature are connected by a simple mathematical relation, in which the coefficients are of the order of magnitude unity". Thus if N_i, N_j are any two of the dimensionless numbers we can state the principle in the form:

$$N_i = C_{ij} N_j F_1^{n_{ij}} \tag{10}$$

where $C_{ij} \sim 1$ is a constant and n_{ij} is a positive or negative integral or half-integral number.

Is there Antisymmetry in Atomic and Cosmic Interactions?

As it stands the force ratio F_1 is not a satisfactory expression of the relative magnitudes of the electromagnetic and gravitational interactions. In small-scale systems, as in atomic physics, it is true to say that the electromagnetic interactions predominate to the extent indicated by (2). But matter tends to be electrically neutral, and in large systems the situation is therefore reversed and it is the gravitational interactions which predominate. It can scarcely be said that F_1 is a universal force ratio for it is limited to either atomic-size systems or to a Universe that contains only a single electron and a single proton. For this reason it is interesting to inquire whether we can derive a second force ratio F_2. In the same way as F_1 expresses the predominance of electromagnetic interactions in atomic-size systems, so F_2 will express the predominance of gravitational interactions in cosmic-size systems.

Let us consider a four-particle universe containing two hydrogen atoms in the ground state. This highly simple universe allows a direct comparison between the interactions of atomic and cosmic systems, and has the advantage of acknowledging the basic electrical neutrality of systems larger than those of an atomic size. If the hydrogen atoms are separated by a distance equal to R, then F_1 applies to the atomic regions within the hydrogen atoms, and F_2 applies to the cosmic region containing the two atoms. As the Coulomb force between the atoms is zero we shall use their magnetic moments $\mu = e\hbar/2m_e c$, aligned parallel or anti-parallel in each other's field, for estimating the magnitude of the electromagnetic interaction. Comparing the relative magnitude of the electromagnetic and gravitational forces between the two atoms separated by the cosmic-like distance R, it follows:

$$F_2 = \frac{3\mu^2}{G m_H^2 R^2} = \frac{3m_e}{4\alpha^2 m_p} F_1 \frac{a_0^2}{R^2} \sim F_1^{-1} \tag{11}$$

where $m_H \simeq m_p$ is the mass of the hydrogen atom.

In this elementary universe the electromagnetic interactions predominate by a factor of F_1 in small systems of atomic dimensions, and the gravitational interaction predominates by a factor of F_1 in a large system of cosmic dimensions. These interactions are thus anti-symmetric in magnitude for the smallest and largest systems possible. Although anti-symmetry of interactions in this sense is interesting we must remember that it applies only to a rather artificial universe and that it does not shed any light on the physics underlying the cosmic numbers. However, the concept of symmetry or anti-symmetry is sufficiently satisfying to reinforce our belief that $R/a_0 \sim F_1$ is a fundamental relation in the physical world.

Cosmology and the Cosmic Numbers

If the atomic constants and also $\hbar$ and c are independent of the age of the Universe, then the relation $R/a_0 \sim F_1$ implies that $G \propto R^{-1}$. This dependence of the gravitational constant on the age and radius of the universe has various cosmological consequences and narrows down considerably the number of possible cosmological models.

Mach's principle[5] (inertia depends upon the distribution of mass in the universe), as formulated by Sciama[7] and Brans and Dicke[8], requires that $GM \propto R$ in a uniform universe of actual or observable mass M. Hence, in a non-static universe Mach's principle is only true if the mass varies as: $M \propto R^2$. In the Lyttleton–Bondi[9] charge-excess hypothesis the charge excess per particle is estimated to be 10^{-18} e. According to this hypothesis a cosmic-size system is characterized by $F_2 \sim 1$. This is not in agreement with a principle of anti-symmetry, for according to this principle any charge excess that might exist should be of the order 10^{-40} e.

Of the various cosmological models that have received attention there are three that conform with the relation: $G \propto R^{-1}$. The first is the steady-state universe[10] in which G and R are both constant. Hoyle[11] has shown that:

$$8\pi\rho G T^2 = 3 \tag{12}$$

where ρ is the mean density of matter. The radius of the observable universe is $R = cT$ and its total mass is given by:

$$\frac{M}{m_p} = \frac{Tc^3}{2Gm_p} = F_1 \frac{R}{2a_0} \tag{13}$$

The steady-state theory fulfils in the simplest and therefore perhaps the most satisfying way the conditions laid down by the cosmic numbers.

The second is Dirac's universe[6]. In this model G is constant in 'dynamic time' but varies in 'atomic time'. With GR constant in dynamic time and mass conserved the dynamic units of time and distance are $t^* = t^2/2t_0$, $l^* = lt/t_0$. Using dynamic units Dirac considers an Einstein–de Sitter[12] universe of zero cosmological and curvature constants. Transforming the results back into atomic units we find:

$$2\pi\rho G T^2 = 3 \tag{14}$$

with $R = \tfrac{1}{2}cT$, and:

$$\frac{M}{m_p} = F_1 \frac{R}{4a_0} \tag{15}$$

The age of this universe is $t = \tfrac{1}{3}T$, and it follows that $G \propto t^{-1}$, $R \propto t$, $\rho \propto t^{-1}$, $M \propto t^2$. The geophysical and astrophysical consequences of G varying inversely with atomic time have been discussed by several authors, particularly by Dicke[13], and at the present stage of the discussion the evidence in support of such an effect is not very convincing. Also, N_s given by expression (7) is approximately the number of nucleons in a star, and it is difficult to see how this number can vary as $t^{3/2}$ when mass is conserved.

A third type of universe has been considered by Jordon[14]. In this particular model the metric has a positive curvature constant, and in order that $G \propto t^{-1}$, $R \propto t$, $\rho \propto t^{-1}$, $M \propto t^2$ in a finite universe matter must be continuously created. This type of model has so far not received any great attention; this may be because there is no clear evidence that G has varied in the course of time. We notice that in the steady-state theory the number N_s is constant and this strongly suggests that the creation process operates uniformly throughout space independently of the stars; in Jordan's theory however $N_s \propto t^{3/2}$ and therefore the creation process must operate primarily within the stars.

All three of the foregoing models obey Mach's principle and yet none is in strict conformity with general relativity. The only existing cosmological model consistent with the equations of general relativity and the principles of Mach and Dirac is the original static universe of Einstein's which is now of historical interest only.

Dicke[15] has questioned Dirac's principle on the grounds that one cannot rule out entirely the possibility that the approximate equality of R/a_0 and F_1 might be nothing more than a characteristic of the present epoch. If F_1 is constant and R increases with time in an evolving Universe Dicke estimates that intelligent life appears when $R/a_0 \sim F_1$. But in this discussion we have seen that the relation $R/a_0 \sim F_1$ has associated with it a hierarchy of numbers $F_1{}^n$ which connects the properties of elementary particles with the metrical properties of space-time. Also $R/a_0 \sim F_1$ is equivalent to a form of anti-symmetry of interaction in atomic and cosmic systems. With only the coincidence of R/a_0 and F_1 to consider we might be willing to believe that Dicke is correct, but it is quite another matter to suppose that an ordered sequence of numbers and anti-symmetry (however feebly formulated) is a coincidence of the present epoch. It seems not unreasonable therefore to believe that the cosmic numbers are evidence of the existence of a fundamental unity of the atom and the cosmos.

I thank Prof. H. Bondi, Prof. R. H. Dicke, Prof. P. A. M. Dirac and Dr. W. B. Thompson for their comments.

DIURNAL EFFECTS IN MAGNETIC CONJUGACY AT VERY HIGH LATITUDE

By E. M. WESCOTT and K. B. MATHER

Geophysical Institute, University of Alaska, College, Alaska

FOLLOWING the general confirmation of the concept of conjugacy from $L \approx 2 \cdot 6$ to $L \approx 5$ by magnetic, Earth current, ionospheric, and auroral techniques it was decided to establish a pair of very high latitude stations to examine the phenomenon polewards of the auroral zone[1]. (L values are McIlwain's parameter[2]. In an undistorted dipole field these would be the geocentric distances to the field line in the equatorial plane, expressed in Earth radii.)

A magnetic station was set up in September 1962 at Shepherd Bay on the Boothia Peninsula of northern Canada (geog. co-ords. 68° 48′ N., 93° 24′ W.), which is approximately conjugate to the New Zealand station of Scott Base in Antarctica (geog. co-ords. 77° 51′ S., 166° 45′ E.). The geomagnetic latitudes are approximately 78·3° N. and 79·0° S. respectively, corresponding to $L \approx 26$.

Because of the inclination of the geomagnetic to the spin axis, the Shepherd Bay station leads Scott Base by approximately 6 h 40 min in rotation, with respect to the Sun.

The period September 15–30 has been examined, by visual comparison of the records, for correlation in H and D disturbances at the two stations. It is evident that a considerable degree of correlation persists in the night-time disturbance even at this geomagnetic latitude (upper two sets of magnetograms of Fig. 1). Disturbances had the same times and usually preserved a similar form, as already confirmed for the auroral zone and at lower latitudes.

However, these polar cap stations also exhibit the well-known day-time maximum[3] and for this the correlation is less apparent. To obtain a rough indication of the diurnal behaviour of the correlation, a number was allocated from 0 to 4, by visual comparison, corresponding to zero correlation, poor, moderate, good, and one-to-one, respectively. A number was allocated to each hour of record and the numbers averaged for each hour over all the days examined. The result is shown in Fig. 2, where the averages have been normalized so that unity corresponds to a one-to-one relationship between the two stations.

There is a broad night-time maximum of good correlation, and an inferior maximum of moderate correlation about midday. Points of poor correlation (often zero

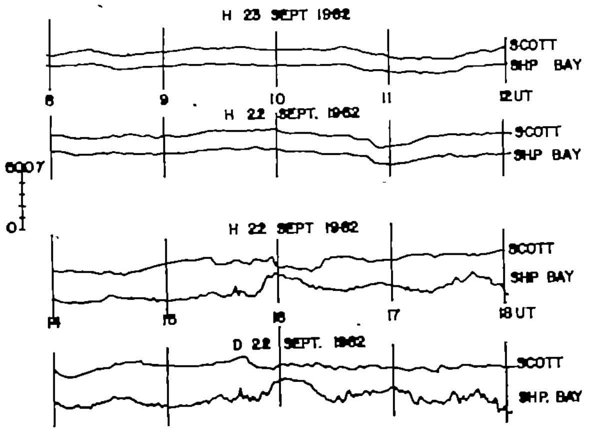

Fig. 1. Comparison of magnetograms from Shepherd Bay and Scott Base. The upper two sets typify good or one-to-one correlation. The lower two sets show poor or zero correlation

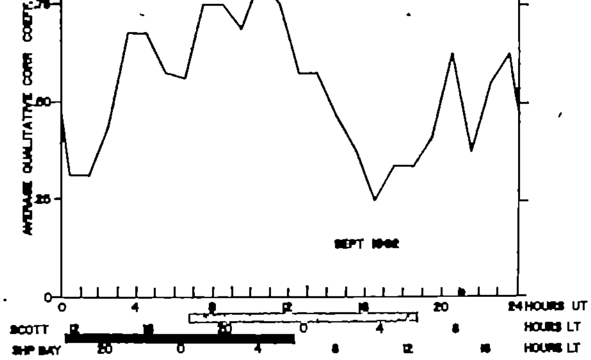

Fig. 2. Variation of correlation between Shepherd Bay and Scott Base magnetic disturbances; U.T. and both local times (L.T.) appear. The shading refers to local night at the two stations (taken as 1800–0600 L.T.)

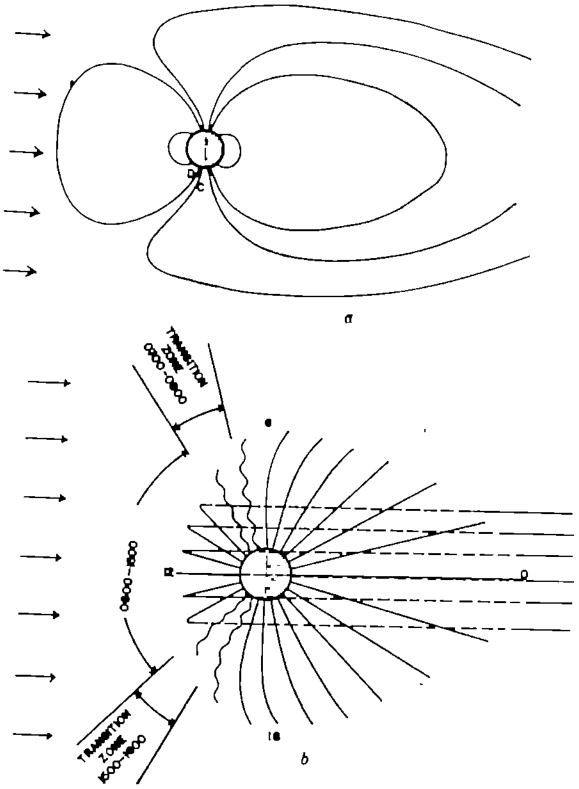

Fig. 3 Distortion of Earth's high-latitude field lines, viewed from the side (above) and from the North Pole (below), due to pressure of solar wind Times given below are 'average local time' (A.L.T.). It is suggested that 'transition zones' occur between alternative long-tail and over-the-pole field paths, and that these time-zones match the times of worst correlation between conjugate stations at very high latitude (Fig 2)

correlation on individual days) divide the two maxima at ~ 0100 U.T. and ~1700 U.T. (see lower two sets of magnetograms, Fig. 1).

One possible interpretation of the foregoing is illustrated in Fig. 3a and b. The night-time maximum corresponds to a field linkage of the conventional dipole form (rather elongated but not grossly distorted), for which conjugacy is well-established in the auroral zone and at lower latitudes. One would expect conjugacy to be maintained around this long field line, though less infallibly than for shorter lines (lower latitudes) where the terrestrial field is stronger. This accords with observation.

As the Earth rotates, the field line approaching the daylight side (0600 h, A.L.T.) encounters steadily increasing resistance from the solar wind[4] and at ~0700–0800 A.L.T. it prefers to link backwards over the polar caps. (A.L.T. here denotes 'average local time', that is, it represents the average orientation of that field plane with respect to the Sun–Earth line at the equinoctial period. 0600 A.L.T. means that Shepherd Bay is 0920 local time (L.T.) and Scott Base is 0240 L.T.) This mode of linkage, which has often been suggested in recent years[5], can be thought of as a 'relaxing' of the system to a more stable configuration of lower potential energy. In fact, the coupled system, magnetosphere plus solar stream, could on this model be treated as a 2-level relaxation oscillator.

From ~ 0800 to ~1500 A.L.T. some degree of conjugacy can again manifest itself via this highly distorted field path, giving rise to the inferior maximum of Fig. 2.

At 1500 or 1600 A.L.T. the field line is encountering sufficiently reduced solar pressure that the normal dipole-type field can be re-assumed. In terms of energy, this corresponds to the returning dominance of magnetic over kinetic energy.

According to the present picture the times 0700–0800 and 1500–1600 A.L.T. might be expected to show poorest correlation between disturbances registered at the two stations, these being the transition or 'relaxation' intervals when a direct field linkage between northern and southern conjugates would be non-existent or erratic. (These are the minima at 0100 and 1700 U.T. in Fig. 2.)

A recent paper by Lebeau and Schlich[6], while not an investigation of a conjugate pair, is relevant because it compares magnetograms from very high latitude stations at approximately the same geomagnetic longitude but differing by about 3° in geomagnetic latitude. The stations, Dumont d'Urville and Charcot (geomag. 75·6° S., 78·3° S., respectively), straddle the zone where a radical change of field linkage might be anticipated, for example, lines *D* and *C* in Fig. 3a.

Correlation coefficients were calculated, based not on the detailed forms of the disturbances but on the magnitude of the disturbance experienced in each hour. Lebeau and Schlich found that: (1) the maximum activity occurred at about midday at both stations; (2) d'Urville was relatively more disturbed than Charcot at all times, but especially so at about midday; (3) the minimum correlation (≈ 0·6) of average activities occurred at midday and the maximum (≈ 0·95) at midnight.

The significant point for us is that although both stations were, on the average, most disturbed about midday, there was least correlation between them at that time. While this might have various interpretations it does not contradict the view that the higher-latitude field line (line *C*, Fig. 3a) has been forced into a different configuration leading to the forward projecting 'horns'. It is then reasonable that lines *C* and *D* should be exposed to relatively independent disturbances.

Another interesting feature of Lebeau and Schlich's result is item (2). This is probably related to the recent finding by O'Brien[7], using *Injun I* data, that the high-latitude termination of electron trapping ($E > 40$ keV) is ~69° ($L \sim 8$) on the night side of the Earth but extends to ~ 75° ($L \sim 16$) on the day side. If the source of the disturbance is associated in some way with the outer 'surface' of the trapped radiation (the 'splash catcher' idea[8]) as appears to be the case for the polar (night-time) aurora, then d'Urville would lie almost under the daytime termination of this surface in the ionosphere, whereas Charcot would lie several degrees polewards.

Referring again to the work of Lebeau and Schlich, it would be helpful to know what correlation exists in the detailed forms of magnetic activity at their two stations, over the course of the day. This might give an indication of the size of the conjugate area at various levels of activity in very high latitudes[9].

Returning to the Scott–Shepherd Bay comparison, one further observation is of interest. Besides the diurnal variation of correlation between the respective magnetograms there is a diurnal variation in the relative intensity of magnetic disturbance, which is best discussed in terms of local time of each station. The amplitude is greater at Shepherd Bay at ~1000 h (Shepherd L.T.), and is greater at Scott at ~ 1300–1400 h (Scott L.T.).

This is explainable in terms of the 'precessional' motion of the Earth's magnetic axis about the spin axis. At 1000 Shepherd L.T. the field line through Shepherd Bay is tilted downwards, with respect to the Sun–Earth line, exposing a greater length of field line, which is therefore presumably more vulnerable to solar shocks at its northern end. At 1300–1400 Scott L.T. the tilt is the other way, the 'underside' of the field being more exposed to the Sun, so one might expect the Scott station to receive the stronger signal, as observed. In either case the enhanced effect is probably due to the combination of circumstances: (1) greater exposure of one 'horn'; (2) shielding of the other 'horn' by the intervening (stronger) magnetic field. But there may well be other factors.

The results presented here were obtained during an equinoctial study, and the argument used in the previous paragraph predicts that a seasonal effect on the relative magnitudes of conjugate disturbances at Shepherd and

Scott should be observed as the year proceeds. As the December solstice approaches the much greater extremes of tilt of the axis (23·50° ± 11° for a centred dipole) should further enhance the signal at Scott relative to Shepherd Bay. The reverse would apply in June.

We must emphasize that the results reported here are very preliminary. Considerably more data, and the calculation of mathematical correlation coefficients, are needed to place the information contained in Fig. 2 on a firm basis.

Data from Scott Base were obtained through the courtesy of Dr. A. L. Cullington, Superintendent of the Magnetic Survey, Department of Scientific and Industrial Research. New Zealand. Equipment at Shepherd Bay was operated by *DEW* line personnel with the co-operation of the Defence Research Board of Canada. This work was sponsored by the Air Force Cambridge Research Laboratories, Office of Aerospace Research, under contract *AF* 19(604)–6180.

QUANTITATIVE DIFFERENTIAL THERMAL ANALYSIS: HEATS AND RATES OF SOLID-LIQUID TRANSITIONS

By Dr. D. M. SPEROS and R. L. WOODHOUSE

Lamp Research Laboratory, General Electric Co., Nela Park, Cleveland, Ohio

THE reduction of differential thermal analysis to a firm quantitative basis appears of such potential usefulness that numerous attempts have been made to bring it about[1]. The scope of a solution to this problem is being examined. This solution essentially effects a temperature balance between sample and reference thermocouples while a thermal balance is maintained within the sample structure as follows:

(1) Temperature balance between sample and reference thermocouples. An auxiliary heater is inserted in the sample structure. So long as the sample undergoes no change in heat content, ΔH, the heater input is kept at zero or some low constant value. When such a change begins to occur, the input to the heater is increased or decreased for an endothermic or exothermic process respectively. This is done in such a manner that the temperature difference between the sample and reference thermocouples is maintained at the same value as before the change began (Fig. 1). It follows that the change in the electrical energy input, ΔQ, required to accomplish this (Fig. 2), is related to ΔH. However, unless the gains in and losses of heat by the sample structure from and to the surroundings are made to be equal, ΔQ will equal ΔH only fortuitously.

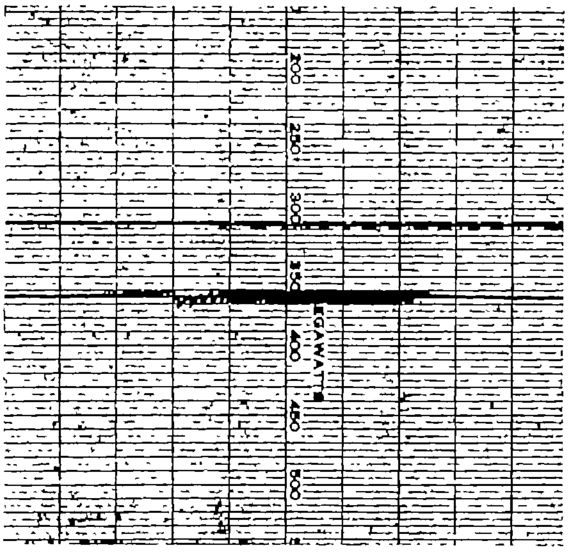

Fig. 1. The appearance of electrically compensated thermal process (fusion of aluminium) on otherwise normal differential thermal analysis record. Heating rate: 0·07° C/min; abscissa; 5 mm/division; ordinate; 0·03° C/division

(2) Thermal balance within the sample structure. In order to obtain a general idea of what the condition $\Delta Q = \Delta H$ entails, the arrangement of Fig. 3 is imagined in which dimensionless heat source H, heat sink S (such as a melting sample) and thermocouple T_s are embedded in a solid which is immersed in a gas. The thermal balance condition:

$$\frac{dH}{dt} = k(T_h - T_m) + \frac{dG}{dt} = k(T_h - T_m) + \frac{dL}{dt} = \frac{dQ}{dt} \qquad (1)$$

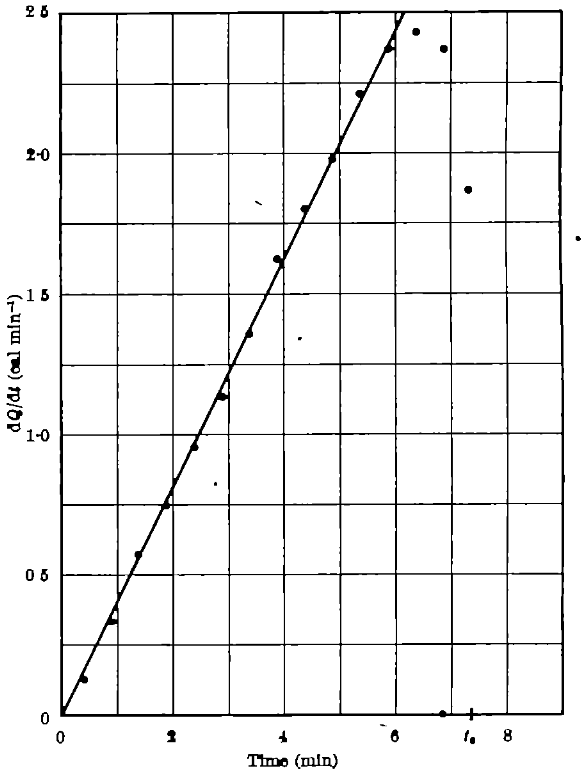

Fig. 2. The rate of electrical energy input into the sample heater as a function of time in order to compensate a thermal process (fusion of tin). Full line; theoretical; points; experimental

where T_m = melting point, T_h = heater temperature and $\frac{dG}{dt}$, $\frac{dL}{dt}$ the rates of extraneous gain in and loss of heat respectively, when considered in conjunction with the appropriate relations[1] of heat transfer, yields:

$$\frac{dG/dt}{dL/dt} = \Delta = \frac{T - T_m}{T_h - T} = \frac{R + rd}{R + r'd'} \qquad (2)$$

where T = gas temperature, d, d' = distances of sample and heater respectively from the adjacent walls of the solid and R, r, R', r' = heat resistance constants[1]. The condition of compatibility between equation (2) and the temperature balance condition, namely, $T = T_c = T_r$, where T_r = the temperature of the reference thermocouple, yields:

$$\frac{D}{D'} = \Delta \qquad (3)$$

where D, D' = distances sample – thermocouple and heater-thermocouple, and Δ is already defined by equation (2).

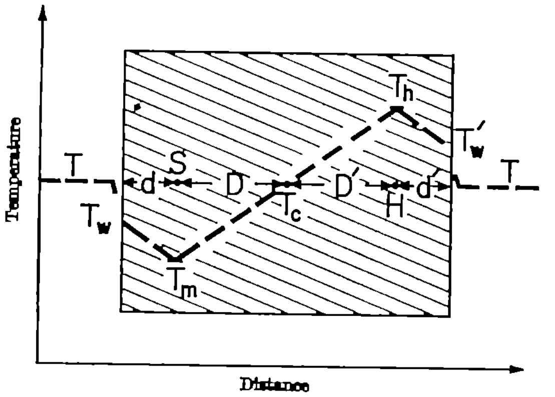

Fig. 3. Thermal balance within imaginary sample structure

For exothermic processes involving initially constant input to H, the foregoing are simplified in that the sum of $\frac{dL}{dt}$ from H and S is held constant before, during and after the process.

Equations (2) and (3) indicate that, even for the idealized model of Fig. 3, the requirements for equality between electrical and process energies are strict. If, for example, $\frac{D}{D'} \neq 1$, then $\Delta Q \neq \Delta H$ even if the result of Fig. 1 is obtained. However, these equations indicate that, in principle, it is possible to adjust or balance the sample structure until $\Delta = 1$ by varying the parameters d, d', D and D' and if necessary R, R', r and r'. The apparent alternative of operating with a known $\Delta \neq 1$ found by calibration is, as will be seen, normally unnecessary.

A practical arrangement that obeys or approximates the general ideas conveyed by equations (2) and (3) may possibly take a number of forms. The approach preferred here was to fold the arrangement of Fig. 3 on itself in the sense of surrounding the sample by the heater (Fig. 4). The outer surface temperature of the heater is kept at T or made to oscillate equally above and below T (Fig. 1), so that for the entire structure $\int dG \simeq \int dL \sim 0$. This is done either: (a) by manually switching the heater on and off at constant power input, the duration of each pulse being such (usually more than 1 sec) that T_c oscillates equally above and below T (Fig. 1); or (b) by adjusting the power either manually or automatically, as by utilizing an electronic controller (work in progress). For the former method the amplitude of oscillations is kept normally below 0·03° C = 1/16 in. pen travel on the recorder. The total 'power on' time is found by a stop-watch or a recorder.

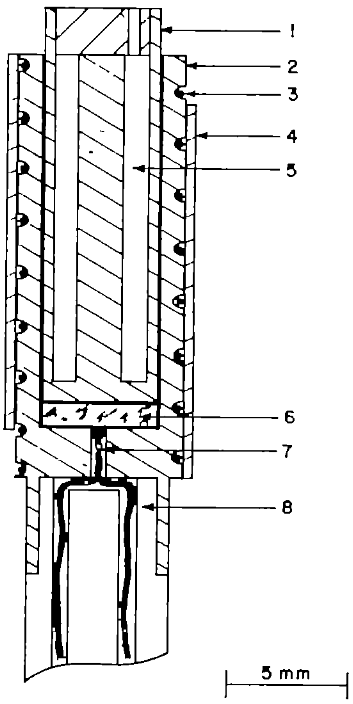

Fig. 4. Cross-section of sample structure: 1, sample container (material compatible with sample); 2, heater casing (nickel); 3, ceramic-coated heater wire (tungsten); 4, heater shield (nickel); 5, sample; 6, insulator (silica); 7, Pt-Pt: 13 Rh thermocouple; 8, ceramic conduit and support (porcelain)

The 'distance' between the thermocouple and the sample container (the concept conveyed by equation (3)) is adjusted until the correct heat of fusion of a substance such as lead is obtained. In order to have a compact design, this distance is increased, not by placing the sample far from the thermocouple, but by inserting a wafer of quartz 1·5 mm in thickness between the two. The bearing of equation (3) is illustrated by the fact that if no insulator is used at all the error becomes + 2 per cent; if the thermocouple is in direct contact with the sample container, but not with the heater casing, the error amounts to + 10 per cent or more depending on the intimacy of the contact; if the thickness of the quartz is increased the error becomes negative, amounting to − 8 per cent for a quartz thickness of 10 mm.

Complete lack of electrical interference between the thermocouple (μV) circuit and the heater circuit is of course necessary.

Once the sample structure was balanced, using lead, the correct heats of fusion were obtained without further adjustment of the sample structure for aluminium, tin and sodium nitrate, thus covering a useful range of temperature (Table 1). Sodium nitrate was chosen because of its anomalous melting behaviour[4]. Samples and container materials were of purity exceeding 99·999 per cent except in the case of sodium nitrate, which was 99·98 per cent pure. The materials were handled and weighed, when indicated, in a nitrogen dry box and the fusions performed in purified argon. Table 1 indicates that the results are independent of variations in gas pressure, etc., at least within the limits shown.

For exothermic processes (freezing), the initially constant input to the heater is the same as shown in Table 1. The E.M.F. of the reference thermocouple is then proportionately increased either by supplying an external constant E.M.F. or by utilizing a reference heater, which is normally present, since both sample and reference structures are used for measurements indiscriminately. All substances in Table 1 froze at rates too high for manual compensation because of supercooling. This tendency was arrested in the case of lead by using a container of

Range of heating rates by external furnace: 0·01–0·50° C/min. Range of pressures of argon gas: 378–1,010 mm mercury. Range of area under normal (uncompensated) differential thermal analysis peaks 0·8–1·5 cm^2/Joule.

99·999 per cent nickel. The heat of crystallization found for this sample was within ± 1 per cent of its heat of fusion.

For zero order kinetics, $dn/dt = (1/\Delta H)(dH/dt)$ where n = moles of molten substance, and dH/dt = the rate at which heat energy is actually absorbed by the substance. For a balanced sample structure, $dH/dt = k(T_h - T_m)$. If a linear heating rate is provided by the external furnace, $T_h - T_m = At$. Combining the last three equations results in $dn/dt = (kA/\Delta H)t$ and $dH/dt = kAt$. The last equation on integration yields $k = 2\Delta H/At_0^2$ or:

$$\frac{dH}{dt} = \frac{2\Delta H}{t_0^2} \cdot t$$

where t_0 is the total time required for the fusion. Accordingly, if $dH/dt = dQ/dt$, that is, if the kinetics of the process can be determined by the procedure described here, a plot of the experimental dQ/dt as a function of time should prove to be a straight line with origin at zero and slope equal to $2\Delta H/t_0^2$. Fig. 2 shows that this is so.

ESTIMATION OF MASS-SCATTERING COEFFICIENT OF BIOLOGICAL SAMPLES

By N. H. SARKAR and DR. P. SADHUKHAN

Biophysics Division, Saha Institute of Nuclear Physics, Calcutta 9

DETERMINATION of mass thickness of biological samples, from the contrast in their electron microscope images, has been carried out by many workers[1-14]. Under normal operating conditions the contrast at a given point of the image is governed by the exponential relation[15]:

$$I = I_0 e^{-S\rho t} \tag{1}$$

where I_0 is the intensity of the electron beam incident on the object of mass thickness ρt, ρ being the density of the material and t the thickness of the object in the direction parallel to the incident beam, I is the intensity of the transmitted beam which reaches the image plane and S is the effective total electron-scattering cross-section per gram of the material. By using carbonaceous samples of known diameter and density and measuring their image contrast some authors[8,12] have estimated the values of S under various operating conditions of the electron microscope. For scattering by a single element, the total atomic cross-section σ is related to S by the expression:

$$S = \sigma \frac{N}{A} \tag{2}$$

where N is Avogadro's number and A the atomic weight of the element. Since biological objects consist mainly of carbon, hydrogen, nitrogen and oxygen, and if objects of thickness less than 900 Å are used, we need only be concerned with single scattered electrons[4].

Zeitler and Bahr[7] state that the effect of inelastic scattering can be disregarded in the aperture range of 10^{-3}–10^{-4} radians. Some recent approaches to this situation have been taken by Valentine[16] and Burge and Silvester[12]. The experimental values of S obtained by Burge and Silvester[12] show that the effect of inelastic scattering cannot be disregarded in the aperture range of 10^{-2}–10^{-3} radians. Moreover, inelastic scattering is more predominant than the elastic scattering in the aforementioned range. But, if one takes into account both the effects, the discrepancy between theoretical and Liesegang's experimental measurement of contrast[17] cannot be explained. However, only the effect of elastic scattering calculated from Lenz's[18] equation with R, the atomic radius, from the Wentzel model fit excellently the experimental results of Liesegang[17]. Table 1 shows the comparison of measured contrast at 60 kV with theory. Table 2 shows the comparison of our experimentally determined S values with those calculated from Lenz's expression for elastic scattering cross-section of carbon atom with R from the Wentzel model. The theoretical and experimental results are in good agreement.

The biological samples studied are the cell membranes of: (*a*) *Escherichia coli* (30); (*b*) human red blood cell (30); (*c*) *Leishmania donovani* (30); (*d*) *E. coli* bacteriophage tail (30); (*e*) tobacco mosaic virus (30); (*f*) yeast ribonucleo-protein (100); (*g*) polystyrene latex (30). The number against each specimen denotes the number of particles examined.

For the preparation of cell membranes, purified normal cells in each case were disrupted by chemical means to remove the cellular contents. The cell membranes, after separation, were collected on carbon-coated grids, dried up and thereby we obtained collapsed cell membranes. For the preparation of *E. coli* bacteriophage the modified technique of Hillier *et al.*[19] as developed by Guha[20] was

Table 1. THEORETICAL VALUES OF CONTRAST OF A 280 Å THICK CARBON FILM AT 60 KV WITH $\theta = 10^{-3}$ RADIANS, ASSUMING $\rho = 1·6$ G CM^{-3}

Atomic radius from:	Contrast in percentage taking into account. Elastic scattering cross-section	Inelastic scattering cross-section	Total scattering cross-section
Wentzel model	18·3*	11·9	28·0
Diamagnetic susceptibility measurement	13 6	9·9	22·2
Hartree model	25·0	14·3	35·7

* Liesegang's[17] measured value of contrast in percentage is 17 5

followed. TMV, yeast ribonucleo-protein and monodisperse polystyrene latex particles were supplied by the Rothamsted Experimental Station, the Distillers Co., Ltd., Edinburgh, and Dow Chemical Co., Midland, United States, respectively.

The electron microscopic observations and photographs were made under Siemens Elmiskop 1, with a 60-kV electron beam at an objective aperture angle of $9\cdot124 \times 10^{-3}$ radians, and afterwards photographed on Ilford process plates. After due processing of the plates, the photographic densities D and D_0 in the imaged region and in the background, respectively, were measured with a micro-densitometer. For the photographic negatives used it was found from a previous experiment that the γ-value under the foregoing conditions was 2·8 with the photographic density-range 1·5–3·0. It is well known that the measured densities D_0 and D are related to the corresponding electron densities by the relation:

$$D_0 - D = \log_{10} (I_0/I) \qquad (3)$$

From (1) and (3) with $\gamma = 2\cdot8$ we get:

$$S = 0\cdot82 \,.\, (D_0 - D)/\rho\, t \,.\, \text{cm}^2\ \text{g}^{-1} \qquad (4)$$

Thus, knowing mass thickness of the specimens, the corresponding S values for them are calculated as shown in Table 2. The $D_0 - D$ values of this table for the *E. coli*, red blood cells and *L. donovani* membranes correspond to twice the membrane thickness, as the two membranes collapse together during preparation and provide the photographic density. So half these $D_0 - D$ values correspond to thickness of a single membrane. Separate values of D_0 and D are not shown in Table 2, but the measured values of them are well within the range 1·5–3·0.

Table 2. VALUES OF S

Specimen	Thickness (t) (Å) from indirect measurements	Density (ρ) (g cm^{-3}) from indirect measurements	Measured $D_0 - D$	Experimental S* cm^2 g^{-1} × 10^{-4}
E. coli membrane	125 (21)†	1·30 (27)	0·197	4·96
RBC membrane	200 (22)	1·30 (27)	0·282	4·45
L. donovani membrane	250 (23)	1·30 (27)	0·342	4·32
TMV	150 (24)	1·37 (28)	0·103	4·12
Yeast RNP	200 (25)	1·50 (29)	0·162	4·42
E. coli bacteriophage tail	252 (20)	1·30 (27)	0·187	4·68
Polystyrene latex	880 (26)	1·05 (12)	0·501	4·45

* The theoretical S (elastic) value for the carbon atom in our experimental conditions is $4\cdot61 \times 10^4$ cm^2 g^{-1}.

† The number within brackets denotes the reference from which the corresponding value is taken

From the comparison of experimental and theoretical S values it is suggestive that only elastic scattering effect is responsible for contrast consideration, at least at the aforementioned operating condition of the microscope, though theoretically the inelastic scattering effect is 67 per cent to that of elastic effect. In Table 1 calculations of contrast in percentage have been made on different models and compared with the experimental value in order to show the merits of the different models for practical purposes. It is seen that Lenz's[18] formula with R from the Wentzel model is a suitable one. The foregoing experimental procedure is also useful for the determination of density of biological samples[13] of known thickness and vice versa. Here a knowledge of theoretical scattering cross-section is necessary, and thus, if the elastic scattering cross-section for a carbon atom is calculated from Lenz's formula with Wentzel radius, the thickness or density values can be found from equation (4) with some confidence, provided the microscope is operated at 60 kV and at an aperture angle near about 10^{-3} radians.

We thank Prof. N. N. Das Gupta, of the University of Calcutta, for his interest in this work, and Mr. M. L. De for helpful criticisms. We also thank Mrs. J. Chackraborty and Messrs. S. B. Bhattacharjee and K. N. Bhattacharjee for help in preparation of some of the specimens. One of us (P. S.) thanks the Ministry of Scientific Research and Cultural Affairs for financial assistance.

BLOCK OF INSULIN SECRETION FROM THE PANCREAS BY D-MANNOHEPTULOSE

By DR. H. G. COORE and DR. P. J. RANDLE
Department of Biochemistry, University of Cambridge
AND
PROF. ERNST SIMON, DR. PERETZ F. KRAICER and PROF. M. C. SHELESNYAK
Endocrine and Reproduction Physiology, Weizmann Institute of Science, Rehovoth, Israel

A TRANSIENT diabetic state can be induced in the rat by a single injection of the seven carbon sugar D-mannoheptulose[1]. Kraicer, Simon and Shelesnyak[2] have suggested that mannoheptulose induces this diabetic state by interfering with the secretion of insulin by the pancreatic islets in response to glucose. An *in vitro* technique suitable for examining the effect of substances on the secretion of insulin utilizing pieces of rabbit pancreas has recently been described[3]. This technique has now been used for investigating the effect of mannoheptulose on insulin secretion induced by glucose. To justify the use of pancreatic tissue of the rabbit, evidence is presented that the rabbit exhibits the same physiological response to mannoheptulose as the rat.

The effect of mannoheptulose on blood glucose concentration was investigated in six male adult rabbits, body-

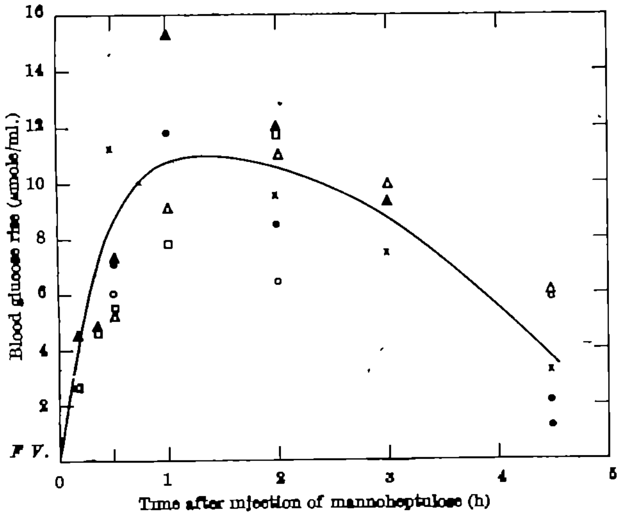

Fig. 1. Increase of glucose concentration in blood after administration of mannoheptulose (intravenously, 2 g/kg) to fasted rabbits. Each rabbit is represented by a different symbol. The curve joins the means (*F.V.*, fasting value)

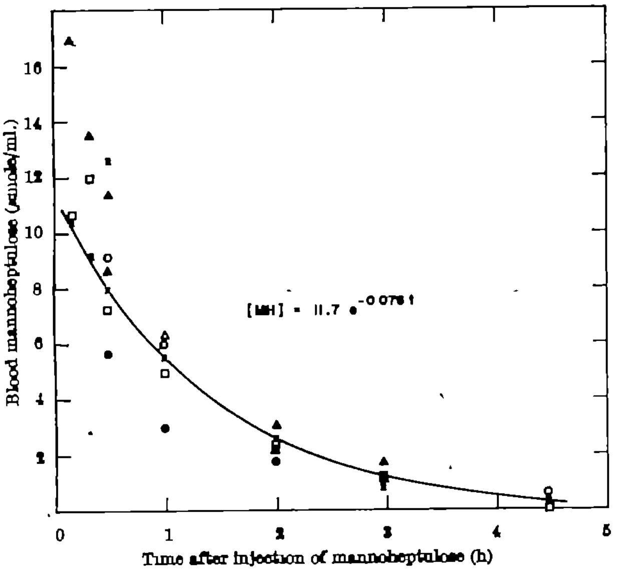

Fig. 2. Concentration of mannoheptulose in blood after administration of mannoheptulose (intravenously, 2 g/kg) to rabbits. The curve was calculated by regression analysis

weight (mean ± *S.D.*) 1·6 ± 0·2 kg. The animals were deprived of food for 24 h and injected intravenously with 2 g/kg of D-mannoheptulose in 1–7 ml. of isotonic sodium chloride. Blood samples, taken from the contralateral ear vein, were analysed for total reducing sugar[4] and mannoheptulose[5], glucose concentration being obtained by difference. Chromatography of concentrated blood filtrates by the method of Nordal and Benson[6] confirmed that mannoheptulose and glucose were the only sugars detectable.

The effect of D-mannoheptulose on insulin secretion was examined as follows. Adult male rabbits deprived of solid food (but with free access to 5 per cent aqueous glucose) for 15–18 h were rapidly anaesthetized with 300 mg hexobarbitone sodium by ear vein. The body and tail of the pancreas were quickly removed and dropped into Krebs supplemented medium[7] gassed with oxygen + carbon dioxide, 95 : 5 (physiological saline medium supplemented with 5 m.equiv./l. sodium L-glutamate, fumerate and pyruvate and also Armour bovine plasma albumin, fraction V, 2 mg/ml.). The pancreas was divided into pieces weighing 100–300 mg with exclusion of obvious non-pancreatic tissue and pre-incubated for 30 min in medium (see foregoing) containing glucose 0·6 mg/ml. After washing with the same medium each piece was transferred to a stoppered pot containing 3 ml. of medium and subjected to a sequence of five separate incubations of 15- or 30-min duration in media containing D-glucose, 0·6 mg/ml., 3 mg/ml., 0·6 mg/ml., 0·6 mg/ml., and 3 mg/ml. (referred to as phases 1–5). In experiments with D-mannoheptulose the sugar was added to a concentration of 3 mg/ml. in phases 4 and 5. Insulin was estimated in residual incubation media from all except the third phase of the sequence by immunoassay[8]. This experimental design was chosen because earlier experience[8] showed that the output of insulin in response to a high concentration of glucose (3 mg/ml.) measured by the difference in output in phases 1 and 2 can be repeated (phases 4 and 5) after a rest period (phase 3). This technique permits each piece of pancreas to be used as its own control and the effect of mannoheptulose to be ascertained by comparing output of insulin in phases 4 and 5 (when the sugar was present) with that in phases 1 and 2 (when the sugar was absent).

For the *in vivo* experiments the results were as follows. The blood glucose concentration following injection of mannoheptulose is shown in Fig. 1. The blood glucose rose to a maximal concentration of 300 ± 40 mg/100 ml. (mean ± *S.E.*) at 1 h after injection (mean fasting value, 100 mg/100 ml.) and remained elevated for more than 4½ h. The blood mannoheptulose fell exponentially, being halved every 55 min (Fig. 2).

For the *in vitro* experiments the average output of insulin in control experiments by six pieces of rabbit pancreas was enhanced by increasing the concentration of glucose in the medium (0·6–3 mg/ml.) from 4·1 to 18·3 mμg insulin/min/piece of pancreas in the first two phases of incubation and from 4·1 to 27 in the last two phases (1 mμg = 10^{-9} g). This confirms, as mentioned previously, that the response to glucose can be repeated a second time. In the presence of mannoheptulose (3 mg/ml.) the average output of insulin was not increased by raising the concentration of glucose in the medium from 0·6 to 3 mg/ml. (outputs of 3·5 and 3·5 mμg insulin/min/piece of pancreas in phases 4 and 5) in spite of the fact that the same pieces had shown a good response to glucose in phases 1 and 2 (outputs 3·5 and 12·5 mμg/min). The statistical significance of these changes has been shown by comparing the ratios (phases 1–2 and 4–5) of the parameter of the insulin assay method used (the radioactivity of the insulin-antibody complex which is inversely related to insulin concentration). In the control series the ratios (mean ± *S.E.*) were 2·45 ± 0·45 and 3·10 ± 0·31 (t for difference is 1·2 and $P > 0·3$). In the mannoheptulose series the ratios were 2·13 ± 0·20 and 1·03 ± 0·07 (t for difference is 5·2 and $P < 0·001$). We conclude that D-mannoheptulose completely suppressed the stimulating effect of D-glucose on insulin output by isolated rabbit pancreas in these experiments without affecting the small output of insulin at a low glucose concentration.

The conclusion of Kraicer, Simon and Schelesnyak[9] that mannoheptulose inhibited the secretion of insulin from the pancreatic β-cells was based on the apparent experimental exclusion of alternative explanations for the hyperglycaemia and ketonaemia following its injection into intact animals. Thus, mannoheptulose did not reduce the effect of injected insulin on blood glucose and ketone bodies of the intact rat[9] or further elevate these parameters in the pancreatectomized animal[9]. The absence of an effect on peripheral glucose uptake in the presence and absence of insulin was also shown with several tissues from the rat tested *in vitro*[10]. There was evidently no net glycogenolysis induced by mannoheptulose since the glycogen content of liver and to a lesser extent kidney and muscle was increased 4 h after its injection in the rat[1]. It was also not possible for conversion of mannoheptulose to glucose to account quantitatively for the hyperglycaemia.

The increment in blood glucose seemed to be due largely to gluconeogenesis since in the starved rats used in the earlier experiments liver glycogen would have been very low. Furthermore, mannoheptulose injection was accompanied by a rise of urinary non-protein nitrogen in intact fasted rats[11] and a further elevation of the blood non-protein nitrogen in nephrectomized animals[9]. The necessity for circulating corticosteroids in the experimental animals if the diabetogenic effects of mannoheptulose were to be exhibited[11] was interpreted as being a necessary condition for adequate gluconeogenesis. The present experiments with rabbits furnish direct evidence for the inhibitory effect of mannoheptulose on insulin secretion but leave open the possibility of an additional effect of the sugar on gluconeogenesis through some other mechanism.

Since conventional metabolic studies on mammalian β-cells are not feasible because of their relative scarcity in pancreatic tissue, the metabolic role of mannoheptulose can only be readily defined using other tissues and work along this line is in progress. If a pathway of metabolism or an enzyme system affected by mannoheptulose were defined this would provide a valuable clue to the mechanism whereby glucose stimulates insulin release from β-cells.

INDUCED ARTERIAL OSCILLATIONS OF BLOOD PRESSURE AS A METHOD FOR INVESTIGATING REGULATION OF LEVEL OF BLOOD PRESSURE

By PROF. P. RUDOMIN and PROF. L. MACPHERSON

Department of Physiology, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional, México 14, D.F.

THE existence of homeostatic systems which control arterial blood pressure implies a stable equilibrium-level for a given physiological state; if the pressure is displaced from this value, the systems will oppose the effect of the imposed change.

In the method described here, the system was displaced from its original equilibrium state; its tendency to return to the original condition was then observed. This displacement was achieved by applying periodic trains of electrical stimuli to the central end of the rabbit's aortic depressor nerve, thus causing the mean value of the resulting arterial pressure oscillation to fall with respect to the original equilibrium value. The duration of the stimulus trains was controlled by the arterial pressure itself: when as a result of depressor stimulation the pressure fell, at a minimum pre-determined value the stimulus ceased; the pressure then rose, and at a maximum pre-determined value the stimulus recommenced. The cycle then repeated itself.

The arterial pressure was measured from a common carotid artery with a capacitance transducer coupled to a gated beam discriminator[1]. The output voltage of the latter was monitored by a Schmitt trigger circuit which changed state at the predetermined pressure values, thereby actuating a relay which connected or disconnected the stimulator in the required manner.

Simultaneous pressure, ECG, heart rate and stimulus records were made.

The experiments were carried out on rabbits anaesthetized with sodium pentobarbital (30 mg/kg body-weight), or under deep ether anaesthesia during the surgical phase, a local anaesthetic being applied to the wounds. In all experiments the animals were paralysed with gallamine triethiodide ('Flaxedil'), maintained with constant pulmonary ventilation, both depressor nerves sectioned, and both common carotid arteries tied.

The following results were obtained: on commencement of a series, the pattern of oscillation (henceforth referred to as 'Pattern *P*') was characterized by short stimulation periods and long non-stimulation periods. The first four oscillations shown in Fig. 1, or those in Fig. 2*A*, illustrate typical examples of this pattern.

Pattern *P* gradually shifted during a series in the direction of Pattern *S*, characterized by long stimulation periods and short non-stimulation periods. Pattern *S* can be observed in the second part of Fig. 1, and in part *C* of Fig. 2. Frequently the arterial blood pressure did not fall sufficiently to interrupt the stimulus, whereupon the oscillation ceased. This was regarded as a marked tendency of the system to move in the *P*–*S* direction (Fig. 1). On many occasions when this 'escape' occurred no further oscillations were produced; if the stimulus were then disconnected, the blood pressure rose transiently above its final normal resting value. After a rest period, oscillations could usually be restored on re-application of the stimulus.

Once the system had escaped from the oscillation induced by stimulation of one of the depressor nerves, immediate alternative stimulation of the other depressor did not renew the oscillation, although previously the stimulation of either depressor had caused similar arterial blood pressure oscillations.

'Spontaneous' escapes or *P*–*S* changes occurred frequently in non-anaesthetized animals, and generally coincided with insufficient curarization. These changes were rarely observed when the animals were anaesthetized with pentobarbital.

While oscillating, the system manifested an increased sensitivity to some stimuli: limb flexion, light tactile

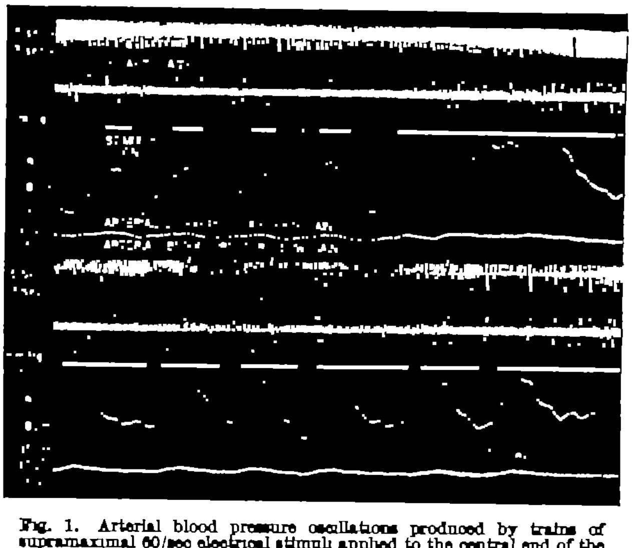

Fig. 1. Arterial blood pressure oscillations produced by trains of supramaximal 60/sec electrical stimuli applied to the central end of the left depressor. Rabbit (1·5 kg) anaesthetized initially with ether, atropinized. Respiration pump stroke volume 150 c.c., pumping rate 34/min. The series illustrated began 1 min before the last four (shown) typical oscillations. The original undisturbed mean arterial pressure was 90 mm mercury. Both parts of the figure are continuous

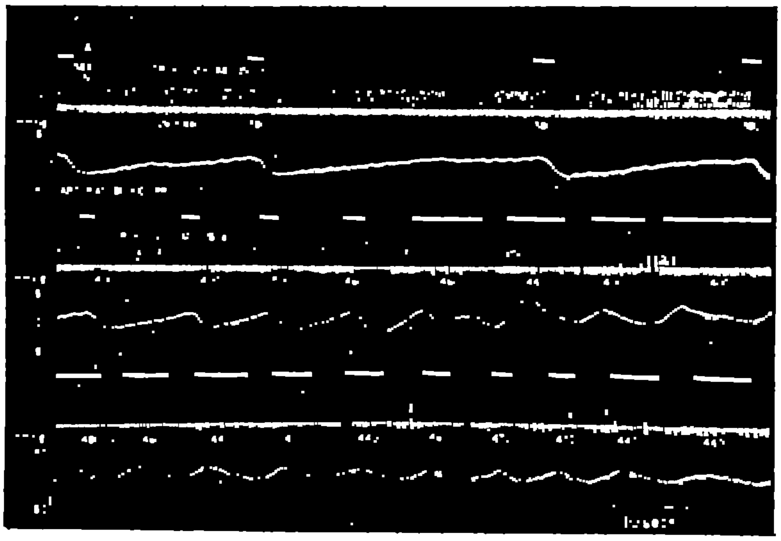

Fig. 2. Arterial blood pressure oscillations produced by trains of supramaximal electrical stimuli applied to the central end of both depressors. Rabbit (1·5 kg) anæsthetized initially with ether. In *A* the respiration pump stroke volume was 150 c.c., pumping-rate 34/min. In *B* at moment indicated by arrow, the stroke volume was reduced to 125 c.c. Between *A* and *B* a part of the ultimate cycle is not shown, identical in all respects to the preceding ones. *B* and *C* are continuous. The first number below the ECG record indicates the control duration of the cardiac cycle, and the remainder the maximum durations resulting from the stimulation of both depressors. The series illustrated began three minutes before the (shown) typical oscillations of part *A*. The original undisturbed mean arterial pressure was 130 mm mercury

stimuli or intravenous injections of 10–20 μg potassium cyanide produced a marked *P–S* pattern change (similar to the example in Fig. 1.) These stimuli did not produce observable changes in arterial pressure when the system was in repose.

As an example of a *P–S* change, Fig. 2 shows the result of hypoventilation on the mode of oscillation: part *A* of Fig. 2 illustrates the pattern obtained with a ventilation of 150 c.c. At the commencement of part *B* the ventilation was reduced to 125 c.c., a resulting shortened non-stimulation period was rapidly observed, as can be seen in the first three oscillations after ventilation reduction, whereas the maximum and minimum arterial blood pressure values have not yet changed appreciably.

Hyperventilation produced a change of the oscillation pattern in the opposite direction.

Besides the hypotension which resulted from depressor stimulation, a diminution of heart rate also took place. During escape, or a *P–S* change, reflex bradycardia did not decrease: on the contrary, it frequently increased. In atropinized and vagotomized animals, a similar change of pattern in the *P–S* direction was always obtained, thus showing that the *P–S* change is independent of the heart rate.

The *P–S* change cannot be satisfactorily explained as due to 'system fatigue'; a more probable interpretation might be that there is a 'build-up' of vasoconstrictor sympathetic activity which tends to suppress the oscillations. This is supported by the fact that any stimulus which is known to increase sympathetic activity also accelerates the *P–S* change (hypoventilation, injection of minute doses of potassium cyanide, painful and tactile stimuli, etc.).

The *P–S* change might also be regarded as indicating a specific tendency of the system to return to its original condition of greater stability[2].

Spontaneous *P–S* changes in animals anæsthetized with pentobarbital were infrequent and appeared as a prolongation of the stimulation period without the concomitant shortening of the non-stimulation periods. In addition, the system exhibits a reduced tendency to return towards its original equilibrium. This might be interpreted as a reduction in homeostatic efficiency. It is suggested that pentobarbital anæsthesia diminishes the 'build up' of sympathetic vasoconstrictor activity.

The 'build up' of sympathetic activity might be explained as due to:

(1) The existence of other unknown receptors besides those which were excluded in the present experiments (aortic, vagal and carotid sinus receptors).

(2) The rhythmic application of stimuli. (Alternating inhibitory and excitatory influences on sympathetic activity might produce a gradual increase in the latter as a result of post-inhibitory rebound.)

(3) The application of electrical stimuli to the depressor nerve in place of normal physiological activation.

We thank Drs. A. Rosenblueth and J. Garcia Ramos for their helpful criticism.

SIALIC ACID IN FIBRINOGEN AND 'VULCANIZATION' OF THE FIBRIN CLOT

By K. LAKI and N. CHANDRASEKHAR*

National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Public Health Service,
U.S. Department of Health, Education and Welfare, Bethesda, Md.

According to our present knowledge, during the clotting of fibrinogen thrombin becomes involved in the process twice. First thrombin splits off 3 per cent of fibrinogen in the form of two peptides[1]. These altered fibrinogen molecules, now called fibrin molecules, aggregate to form the primary clot[2] (Fig. 1). In its second interaction thrombin activates a plasma component (the Laki–Lorand factor—various names have been given to this plasma component: fibrin stabilizing factor[17], fibrinase[18], Laki–Lorand factor[19]. Until the exact mode of action of this enzyme is elucidated, it is preferable to use a non-specific name. We refer to it in this article as LLF) into an enzyme[3], which 'vulcanizes' the clot by introducing strong bonds between the fibrin molecules; as a result the clot becomes insoluble in 5 M urea[4]. In normal plasma the insoluble clot is formed. If the LLF is missing from the plasma, the clotting process is incomplete, the 'vulcanization' of the clot does not occur and a tendency for bleeding[5] as well as an impairment of wound healing sets in[6]. It was found by Laki[7] and by others[8–10] that during interaction of thrombin with fibrinogen, not only peptides were liberated but also carbohydrate residues containing mannose and galactose were released. Chandrasekhar *et al.*[11] have recently observed that sialic acid is also liberated during clotting.

* Visiting scientist—National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Public Health Service, U.S. Department of Health, Education and Welfare, Bethesda, Md.

LLFe
(d) Fibrinn(s) → Fibrinn(i) + carbohydrates
(insoluble clot)

Fig. 1

These sugars originate from the carbohydrate moiety of fibrinogen which in the case of bovine fibrinogen amounts to about 3 per cent[7].

Szara and Bagdy[8] found that the release of carbohydrate material goes parallel with the action of thrombin in spite of the fact that thrombin is not a carbohydrate-splitting enzyme. Thus the action of thrombin in liberating carbohydrates can only be indirect. Since fibrinogen preparations, unless specially treated, are contaminated with LLF, it is likely that this enzyme (activated by thrombin) is responsible for the release of carbohydrates from fibrinogen. To test this assumption we modified the carbohydrate moiety of fibrinogen by selectively removing sialic acid with the enzyme sialidase (neuraminidase). Bovine fibrinogen (97 per cent clottable), prepared by the method of Laki[7] was treated with sialidase (from *Vibrio cholerae*) to split off sialic acid. The enzyme-treated fibrinogen was finally separated with ammonium sulphate precipitation. The assays of neutral carbohydrates by the orcinol method[13] and that of sialic acid by the thiobarbiturate method[14] showed that the enzyme removed only the sialic acid residues from fibrinogen. Ultracentrifugal examination revealed that no detectable change occurred in the sedimentation properties of fibrinogen (Fig. 2).

It is seen in Table 1 that clots obtained from sialic acid-free fibrinogen in the presence of fresh human plasma (as the source of LLF) were easily soluble, whereas those from untreated fibrinogen were only sparingly soluble in 5 M urea solution. The fibrin clots from treated fibrinogen were all in solution within 2 h, while much of the clots from the untreated fibrinogen remained insoluble after 24 h and even after 7 days. Experiments using purified LLF kindly supplied by A. G. Loewy also gave similar results. Apparently, the removal of sialic acid from bovine fibrinogen modified the substrate in such a manner that the LLF was no longer able to act on it.

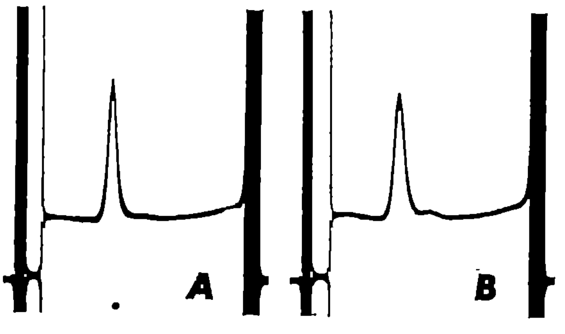

Fig. 2. Ultracentrifuge pattern of native and sialic acid-free fibrinogen. *A*, native fibrinogen, $S_{20,w} = 7.72$. *B*, sialic acid-free fibrinogen, $S_{20,w} = 7.52$.

Table 1. SOLUBILITY OF NORMAL AND SIALIC ACID-FREE FIBRIN CLOTS IN UREA

Duration of incubation of the clots in urea	Optical density at 280 mμ of the dissolved portion of the clots*	
Hours	Normal clots	Sialic acid-free clots
0·5	0·081	0·640
1·0	0·226	0·965
2·0	0·256	1·015

* Corrected for the optical density of the plasma blanks.

The reaction mixture consisted of 1·0 ml. fibrinogen, 1·0 ml. 0·3 M KCl, 0·4 ml. M/5 *tris*–maleate buffer of pH 6·5, 1·4 ml. distilled water, 0·2 ml. M/40 calcium chloride, 0·1 ml. human plasma and 0·02 ml. thrombin. Thrombin and plasma were added simultaneously. Suitable controls, in which plasma and calcium were left out from the reaction mixture, were also run. The clots were allowed to stand at room temperature for 3 h. After the incubation, 4·0 ml of a 10-M urea solution was added to each of the tubes (final urea concentration 5 M) and the clots were shaken uniformly and at definite intervals. 1·0 ml. each of the clear supernatant was taken from the respective tubes at different time intervals, mixed with 4·0 ml. of 0·3 M KCl and the optical density at 280 mμ was measured in a Beckman spectrophotometer. A solution compounded similarly, but without the fibrinogen and plasma in the reaction mixture was used as the blank. Another blank, the plasma blank, was also run, using human plasma in the original reaction mixture, but not the fibrinogen.

Our results reported in this article, coupled with the observation[15] that the activation of LLF goes parallel with an increased release of carbohydrates during clotting, strongly suggest that LLF is an oligosaccharide-splitting enzyme. (Recently, Lorand *et al.*[20] proposed that LLF is a transpeptidase. According to their assumption the peptides released from fibrinogen in the presence and absence of this factor should be different. Recent experiments of J. A. Gladner and A. J. Osbahr in this laboratory in co-operation with A. G. Loewy (Haverford, Pa.)[21] have shown that the peptides released from human fibrinogen using human thrombin and human LLF were identical irrespective of whether the clotting was carried out to produce the soluble or the insoluble clot. This crucial experiment suggests that LLF is not a transpeptidase.)

The introduction of firm bonds between the fibrin molecules as a result of LLF may be due to a Schiff-base like combination between amino groups and carbonyl groups of the carbohydrate residues liberated in the splitting. This possibility is all the more likely, since under certain conditions carbonyl reagents inhibit the clotting of fibrinogen[7]. The inhibition by the carbonyl reagents may be due to a competition for the same amino groups that otherwise would be involved in forming the Schiff-base type bonds between fibrin molecules.

The role of this carbohydrate-splitting enzyme, LLF, in wound healing is still not understood. It is worth while, however, to point out that another carbohydrate-splitting enzyme, β-glucuronidase, shows increased activity in healing wounds[16]. This enzyme acts on mucopolysaccharide, the ground substance of collagen.

RELATIONSHIP OF PLASMA SALICYLATE CONCENTRATION TO URINARY SALICYLATE EXCRETION RATE

By Prof. EINO NELSON and Prof. GERHARD LEVY
School of Pharmacy, State University of New York at Buffalo

CUMMINGS and Martin[1] have reported recently that maximum plasma salicylate-levels after oral doses of aspirin occurred much earlier than maximum urinary excretion rates of salicylate. They referred to similar observations by others and pointed out that this fact has received no special comment.

The colorimetric analysis of salicylate in the urine yields values that must be expressed in terms of apparent salicylate, because both salicylic acid and its metabolite salicyluric acid are measured. If salicyluric acid is excreted in significant amounts, a delayed apparent salicylate excretion peak should be expected, due to the time required for the biosynthesis of the metabolite. On the other hand, a specific assay for salicylic acid should yield a urinary excretion pattern in which the peak excretion rate coincides with plasma salicylate concentration peak. We wish to report the results of experiments which illustrate and elucidate these contentions.

Two adult male subjects ingested 1 g doses of aspirin (dissolved in about 240 ml. of water by the addition of 1 g of sodium bicarbonate) in the morning on empty stomach. Urine collections were made at appropriate times, and aliquots of these were assayed for salicylic acid and salicyluric acid by a combination of the methods of Brodie *et al.*[2] and Trinder[3]. The maximum excretion rate occurred about 2·5 h after administration of the drug (Fig. 1), and more than 90 per cent of the apparent salicylate excreted was in the form of salicyluric acid. The delayed excretion peak can therefore be attributed to the time required for metabolite formation.

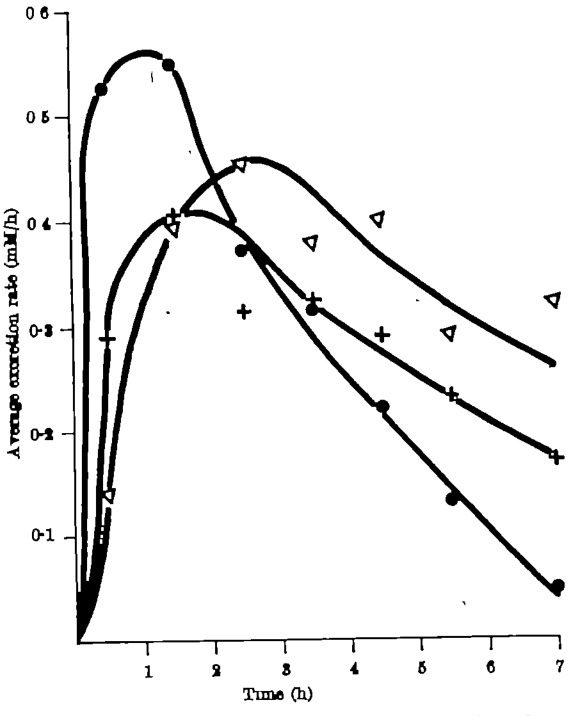

Fig. 1. Salicylate excretion rate after oral ingestion of 1-g doses of aspirin in aqueous solution

▽, salicyluric acid excretion; ●, salicylic acid excretion when urine was alkalized; +, salicyluric acid excretion when urine was alkalized

Unfortunately, the fraction of aspirin excreted as free salicylic acid was too small to determine the time of maximum excretion. This fraction may, however, be increased by making the urine slightly alkaline, because the excretion rate of salicylic acid is increased at higher *p*H. The time of maximum excretion is not affected. The experiment was repeated therefore under conditions in which the urinary *p*H was increased by administration of 21 g of sodium bicarbonate in divided doses over 6 h, beginning 3 h prior to aspirin ingestion. The administration of sodium bicarbonate resulted in urinary *p*H's of 7·6 in one subject and 7·9 in the other. A considerable amount of free salicylic acid was excreted under these conditions, and the maximum excretion rate occurred at about 1 h after administration of the drug (Fig. 1). It is known from other investigations that peak plasma salicylate concentrations also occur about 1 h after oral administration of aspirin in readily absorbable form, as has been pointed out by Cummings and Martin[1].

Maximum excretion of salicyluric acid occurred 1·5–2 h after administration of the drug, which is later than the time of maximum salicylic acid excretion, but somewhat earlier than maximum salicyluric acid excretion in the first experiment. While an increase in urinary *p*H should have no effect on the time of maximum salicylic acid excretion (because salicylic acid excretion rate is directly proportional to the salicylate plasma level), it will modify the time of maximum salicyluric acid excretion. The excretion of this metabolite is the terminal step in a two-step process (biosynthesis followed by excretion). In the dosage used, both these processes can be described by first order kinetics[4]. The rate of excretion of salicyluric acid can be represented, therefore, by the following expression, which gives the rate of accumulation of the product of two consecutive first-order reactions:

$$\frac{\mathrm{d}U}{\mathrm{d}t} = \frac{k_2\, k_1 f S^0}{k_1 - k_2}\left(\exp\,[-k_2 t] - \exp\,[-k_1 t]\right) \qquad (1)$$

In the equation, $\mathrm{d}U/\mathrm{d}t$ represents the salicyluric acid excretion rate, f is the fraction of the ingested dose which will be excreted eventually as salicyluric acid, S^0 is the amount of salicylate in the body after absorption of the dose, t is time, k_1 is the rate constant for biosynthesis of salicyluric acid, and k_2 is the rate constant for urinary excretion of salicyluric acid. The constants k_1 and k_2 have dimensions of reciprocal time. It should be pointed out that the value of fS^0 need not be known for the derivation that follows. If the derivative of equation (1) is obtained and the resulting expression is equated to zero and rearranged, the following equation results:

$$t_{\max} = \frac{\ln(k_2/k_1)}{k_2 - k_1} \qquad (2)$$

where $t_{\max}$ is the time of occurrence of the maximum excretion rate of salicyluric acid. The rate of biosynthesis of salicyluric acid, and therefore k_1, should be independent of sodium bicarbonate ingestion and urinary *p*H. However, the rate of excretion and the excretion rate constant k_2 increase at higher *p*H (ref. 5). Therefore, $t_{\max}$ will be less at higher *p*H's because the value of the right-hand side of equation (2) will decrease as k_2 increases. This is in agreement with the experimental data (Fig. 1).

Cummings and Martin[1] suggest that serum salicylate-levels are disproportionately high (and tissue salicylate-levels are disproportionately low) when the drug is absorbed very rapidly and that therefore 'the relative speed of absorption of aspirin formulations cannot be accurately assessed by comparison of respective plasma salicylate concentrations'. This contradicts commonly accepted principles governing the rate of transfer of drugs from the circulation to the tissues, and could imply the existence of an active and saturable process concerned with the movement of drugs across the membranes of blood vessels. The rate of transfer of salicylate from the circulation to the tissues is understood generally to be a function of concentration gradient (which is essentially equal to plasma salicylate concentration during the absorption phase). This may be modified by plasma protein binding, but in a manner opposite to that suggested by Cummings and Martin, because a greater fraction of salicylate exists in free (diffusible) form at higher concentrations[6,7]. Data are available in the literature in support of these statements. For example, Davison *et al.*[8] determined plasma and brain salicylate-levels after oral administration of aspirin and sodium salicylate to rats. Both drugs were given in rapidly absorbable and more slowly absorbed forms. The ratio of plasma to brain salicylate-levels was actually somewhat lower after administration of the drugs in rapidly absorbed form than after administration of these drugs in more slowly absorbed form. This is probably due to the plasma-protein binding effect already referred to.

Our experimental results and other evidence indicate that both plasma salicylate and urinary excretion data are satisfactory indicators of the relative absorption rate of orally administered salicylates.

MECHANISM OF THE SUCCINIC DEHYDROGENASE CATALYSED REACTION

By PROF. O. GAWRON, A. J. GLAID, JUANITA FRANCISCO and T. P. FONDY

Department of Chemistry, Duquesne University, Pittsburgh, 19, Pa.

IT has been recently demonstrated[1,2] that succinic dehydrogenase acts in a stereospecific fashion with respect to the substrates L-chlorosuccinic acid and L-methylsuccinic acid and it also has been shown that the dehydrogenation effected by the enzyme with succinate[3] and with L-chlorosuccinate[2] is *trans* in nature. The catalysis by the enzyme of the removal of *trans* hydrogens has suggested[3] the possibility that the hydrogens concerned are individually removed. This possibility has been investigated by means of anaerobic exchange experiments with L-chlorosuccinate and with succinate, and it is the province of this communication to report that one of the two hydrogens of a removal *trans* pair is initially exchanged.

Experimental conditions for the exchange of succinate hydrogens with proton of the medium have been defined by Englard and Colowick[4] and it is to be noted that the presence of fumarate is required for the exchange. In a similar manner exchange of the hydrogens of L-chlorosuccinate requires the presence of the oxidized substrate for extensive exchange. Fig. 1 demonstrates the anaerobic rates of exchange at *p*H 7·3, 34° of the hydrogens of L-chlorosuccinate in the presence and absence of chlorofumarate. It is to be noted that the initial rate of exchange catalysed by succinic dehydrogenase is markedly increased by the presence of chlorofumarate. In this connexion it is possible that the rate in the absence of chlorofumarate is affected by the slow dehydrohalogenation of chlorosuccinate in neutral solution, the product being fumarate and the fumarate catalysing the exchange. The true rate in the absence of chlorofumarate may thus be considerably lower than the observed rate. The average amount of deuterium incorporated in the 12- and 24-h samples in the presence of chlorofumarate amounts to 5·1 atom per cent deuterium and since complete exchange of one of the three carbon-bonded hydrogens under the conditions of the experiment, 27·0 per cent deuterium oxide, would yield L-chlorosuccinate with 5·4 atom per cent deuterium, it would seem that only one of the three carbon-bonded hydrogens is exchanged.

To substantiate this point, the distribution of deuterium in exchanged L-chlorosuccinic acid (Table 1) was ascertained by the mass spectrometer. The exchanged L-chlorosuccinic acid was converted to L-chlorosuccinic anhydride with phosphorus pentoxide[5] and the chloroanhydride was then thermally dehydrohalogenated[6] to yield maleic anhydride. The thermal dehydrohalogenation proceeded, essentially, with retention of deuterium and since those hydrogens of L-chlorosuccinic acid, removable by succinic dehydrogenase, are *trans*[2] (when the carboxyl groups are also *trans*) the thermal dehydrohalogenation of L-chlorosuccinic anhydride proceeds in a *cis* fashion, namely:

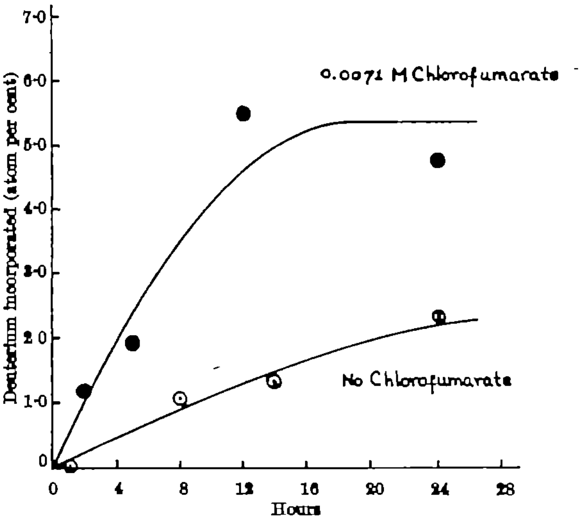

Fig. 1. Rate of incorporation of deuterium into L-chlorosuccinate by anaerobic exchange catalysed by succinic dehydrogenase at *p*H 7·3, 34°. Reaction mixtures were 0·05 M in phosphate buffer, 0·036 M in L-chlorosuccinate, 5·5 × 10^{-4} M in methylene blue and contained 7·5 ml. of the Slater modification of the Keilin–Hartree preparation from horse heart per 140 ml. For each point on the curve 140 ml. of reaction mixture was incubated under nitrogen for the appropriate time period and the reaction stopped by addition of 6 M sulphuric acid to *p*H 1·0. L-Chlorosuccinic acid was then isolated by ether extraction, purified by recrystallization from ethyl acetate and its deuterium content determined by the falling drop method on the water obtained by combustion

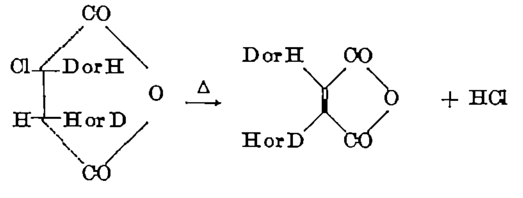

Table 1. DISTRIBUTION* OF DEUTERIUM IN PRODUCTS OBTAINED FROM EXCHANGED L-CHLOROSUCCINIC ACID†

Mass No.	L-Chlorosuccinic anhydride Normal	L-Chlorosuccinic anhydride Exchanged‡	L-Chlorosuccinic anhydride Excess§	Maleic anhydride Normal	Maleic anhydride Exchanged‖	Maleic anhydride Excess§
98	80·2	80·2	—	80·5	80·5	—
99	3·98	17·0	13·0	4·62	17·1	12·5
100	0·80	2·68	1·88	1·08	2·60	1·52

* Relative heights of maleic anhydride parent peaks, 98, 99, 100. L-Chlorosuccinic anhydride also yields these peaks.

† 500 ml. of a reaction mixture, 0·036 M in L-chlorosuccinate, 0·0068 M in chlorofumarate, 0·05 M in phosphate buffer, *p*H 7·6, containing 250 ml. of D_2O and 40 ml. of a Slater enzyme preparation, was incubated at 34° for 4 h. L-Chlorosuccinate, 960 mg, m.p. 179°–180° after lyophilization from water, containing 7·23 per cent deuterium, was obtained by acidification of the reaction mixture to *p*H 1, extraction with ether and recrystallization from ethyl acetate of the crude residue.

‡ Analysis gave 6·40 per cent deuterium, calculated from mass spectral results 5·60 per cent, calculated from deuterium content of exchanged acid 6·02 per cent.

§ To be multiplied by the dilution factor of two, since the exchanged L-chlorosuccinic acid was diluted with an equal weight of normal acid for conversion to L-chlorosuccinic anhydride and maleic anhydride.

‖ Analysis gave 8·22 per cent deuterium, calculated from mass spectral results 8·35 per cent and 7·75 per cent, calculated from deuterium content of exchanged acid 9·00 per cent. The normal maleic anhydride was prepared from normal chlorosuccinic anhydride and both maleic anhydrides contained a small amount of a chlorine-containing impurity.

and the maleic anhydride thus derived from exchanged L-chlorosuccinic acid is suitable for distribution studies. It was also found that L-chlorosuccinic anhydride underwent *cis*-dehydrohalogenation in the mass spectrometer, its 98, 99, 100 mass number pattern being the same (Table 1) as that for maleic anhydride. The results obtained (Table 1) with both L-chlorosuccinic anhydride and maleic anhydride derived from exchanged L-chlorosuccinic acid show that of 100 molecules, 25–26 have undergone exchange of one hydrogen for deuterium and 3–4 exchange of two hydrogens. These results, then, also indicate that succinic dehydrogenase catalysed exchange proceeds by exchange of one of the two hydrogens of a removable pair albeit the second hydrogen may exchange at a decidedly slower rate. From other, longer, exchange experiments, exchanged L-chlorosuccinic acid was converted to dimethyl L-chlorosuccinate (7·1 per cent deuterium found, 6·65 per cent deuterium calculated for complete exchange of one hydrogen), exchanged succinic acid was converted to dimethyl succinate (8·2 per cent deuterium found, 10 per cent deuterium calculated for complete exchange of two of the four hydrogens) and the distribution of deuterium containing molecules in each of these esters was investigated with the mass spectrometer. The distributions, so obtained, are qualitatively in line with the results given here. Quantitative calculation of distributions was considered to be approximate since parent peaks were not obtained and the cracking pattern of the normal esters which was considered as a basis for calculation is, in the case of dimethyl succinate, not consistent with the cracking pattern of the dideuterio-ester and the tetradeuterio-ester[6]. It is of interest to note in connexion with succinate exchange experiments that exchange of one hydrogen by deuterium should lead to observable[7] optical activity in the exchanged succinic acid.

It is clear from the observed distributions that one of the two hydrogens of a removal *trans* pair is exchanged at a much faster rate than the other and it would seem, therefore, that the processes resulting in exchange of both hydrogens are not chemically equivalent. Thus one of the hydrogens might be removed as a proton (rapid exchange) and the other, initially removed as a hydride ion, might afterwards undergo slow exchange.

The requirements for exchange and the distributions of deuterium in exchanged L-chlorosuccinate and exchanged succinate can be rationalized on the basis of either of the following reaction sequences:

$$SH_2 + E_{ox} \rightleftharpoons SH_2 \cdot\cdot E \rightleftharpoons SH^{(+)} + EH \qquad (1)$$

$$SH^{(+)} \rightleftharpoons S + H^+ \qquad (2)$$

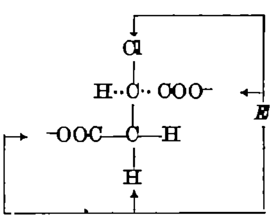
$$EH \rightleftharpoons EH' \rightleftharpoons EH'' \rightleftharpoons E_{red} + H^+ \qquad (3)$$

or:

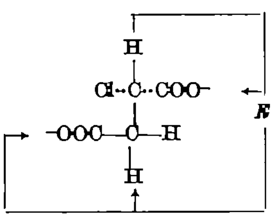
$$SH_2 + E_{ox} \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} SH(-) \cdot\cdot E \rightleftharpoons S + EH \qquad (4)$$

$$EH \rightleftharpoons EH' \rightleftharpoons EH'' \rightleftharpoons E_{red} + H^+ \qquad (5)$$

In these sequences succinate and L-chlorosuccinate are represented by SH_2, fumarate and chlorofumarate are represented by S, oxidized succinic dehydrogenase is represented by E_{ox}, reduced enzyme by E_{red} and the reaction between reduced substrate and oxidized enzyme is written as a hydride ion transfer. In the first sequence, reactions 1, 2 and 3, the products of the initial transfer are written as SH^+, the carbonium derived from reduced substrate by loss of a hydride ion, and as *E*H, enzyme reduced by addition of a hydride ion. Both SH^+ and *E*H react further, SH^+ losing a proton with or without enzymatic intervention to give the oxidized product, S, and *E*H undergoing an internal oxidation, that is, the site originally reduced by the hydride ion undergoes oxidation at the expense of a neighbouring site and the hydrogen atom originally transferred may now exchange with protons of the medium. The second sequence (reactions 4 and 5) differs from the first only in that reaction is initiated by loss of a proton and then followed by hydride ion transfer. The described sequences are consistent with the conditions required for exchange since in the absence of added fumarate or chlorofumarate only the small amount of oxidized substrate produced by the stoichiometric amount of oxidized enzyme, *E*, would be available for the reverse reaction in which H^+ is incorporated, and it is to be expected that under these conditions incorporation of hydrogen would be minimal. Further, the presence of only reduced substrate would keep the enzyme substantially in the reduced state and relatively little catalyst would be avilable for the forward reaction. In the presence of added oxidized substrate, chlorofumarate or succinate, more substrate would be available for reversal of hydride transfer to enzyme and the ratio of oxidized to reduced enzyme would be increased. Since each effect results in an increased rate of reaction at an opposite side of the equilibrium, exchange with the system at equilibrium will be speeded up by the presence of added oxidized substrate. It should also be noted that exchange does not occur with D-chlorosuccinate, either in the presence or absence of chlorofumarate. Since D-chlorosuccinate is a competitive inhibitor of succinic dehydrogenase[1,2], it forms a complex with the enzyme and this complex and the enzyme complex with L-chlorosuccinate can be depicted[2] as:



and

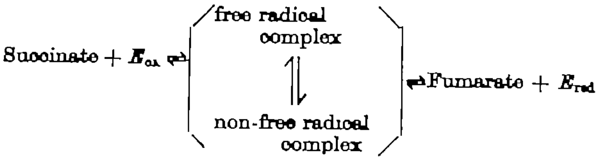


D-Chlorosuccinate complex

L-Chlorosuccinate complex

it is to be noted that the enzyme may attack the α-hydrogen of L-chlorosuccinate but not that of D-chlorosuccinate. On this basis only, experimental evidence not being available at present, it is considered that the α-hydrogen of L-chlorosuccinate is the hydrogen initially attacked by the enzyme. On the basis of the first sequence (initiation by hydride ion transfer) it follows that the *trans* β-hydrogen is initially exchanged and on the basis of the second sequence (initiation by proton transfer) it would follow that initially the α-hydrogen is exchanged. Again, the position of the initially exchanged hydrogen has not yet been experimentally demonstrated.

Hollocher and Commoner[8] have established that a free radical is formed in an anaerobic system consisting of succinic dehydrogenase, succinate and fumarate at equilibrium, all three components being required. From concentration effects of co-substrates on the amount of free radical formed, the following equilibrium reaction scheme was proposed:



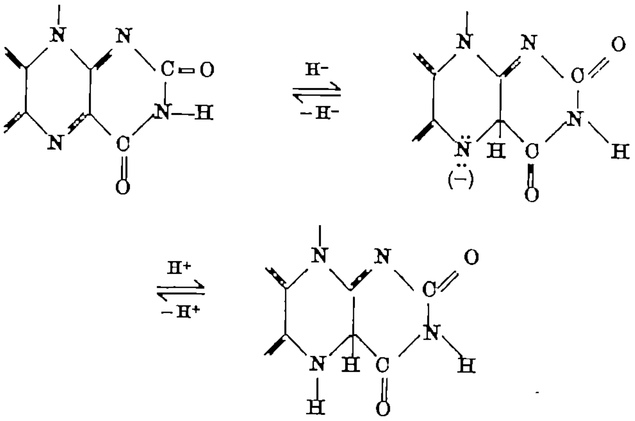
$$\text{Succinate} + E_{\text{ox}} \rightleftharpoons \left(\begin{array}{c} \text{free radical complex} \\ \upharpoonleft\downharpoonright \\ \text{non-free radical complex} \end{array} \right) \rightleftharpoons \text{Fumarate} + E_{\text{red}}$$

The experimental conditions required for the formation of free radical are the same as those required for exchange and the proposed schemes for free radical formation and exchange are similar in outline. It thus seems likely that hydrogen exchange and free radical formation occur by a common pathway and a hypothetical pathway utilizing F for the flavin moiety apparently covalently linked to apoenzyme[9] and Fe^{III} for the oxidation state[10] of iron in oxidized succinic dehydrogenase is given as follows:

$$\text{H}^- \text{ (from substrate)} + F\text{—}E\text{—}\text{Fe}_2^{\text{III}} \rightleftharpoons \text{H}F^{(-)} - E \cdots \text{Fe}_2^{\text{III}} \quad (1)$$

$$\text{H}F^{(-)} - E \cdots \text{Fe}_2^{\text{III}} \rightleftharpoons \text{H}F\cdot - E \cdots \text{Fe}^{\text{II}}, \text{Fe}^{\text{III}}$$
$$\text{H}F\cdot - E\cdot\cdot\text{Fe}^{\text{II}}, \text{Fe}^{\text{III}} \rightleftharpoons F\text{—}E\cdot\cdot\text{Fe}_2^{\text{II}} + \text{H}^+ \quad (2)$$

In this depiction, oxidized and reduced substrates and exchange with SH^+ have been omitted so as to direct attention on the enzyme. It is considered that hydride ion is transferred from substrate to the enzyme, the flavin moiety being the acceptor[11] and being reduced by the two electron transfer to an anion which in turn can reduce by two one-electron transfers two Fe^{III} ions of the four attached to enzyme[12], regenerating oxidized flavin and liberating transferred hydrogen as a proton. This scheme is not inconsistent with the interpretation of free radical data[8] and also provides for exchange of the second hydrogen of a removable *trans* pair at, presumably, a slower rate than exchange of the other (as a proton). This scheme also provides a direct pathway for the anaerobic reduction of DPN by succinate in mitochondria[13] since a hydride ion could be transferred from substrate to flavin to DPN. The intermediate role of flavin between hydrogen transfer and electron transfer also becomes apparent on the basis of the foregoing scheme. The site at which a hydride ion attacks riboflavin is not known and it may well be that hydride is not transferred to one of the two positions at which hydrogen is commonly considered to be attacked in reduced riboflavin[14]. By analogy with alloxan, it may be that riboflavin is attacked, as follows:



It should also be noted that iron–alkyl complexes have recently been reported[15] to undergo reversible removal of a hydride ion and it is possible that similar complexes are operative in the succinic dehydrogenase system.

This investigation was supported by research grant RG-6245 from the Division of General Medical Sciences, U.S. Public Health Service. We thank Dr. T. J. Weismann and Dr. G. Mains for the mass spectral data.

SOCIAL FORCES DETERMINING SPACING AND HEAD ORIENTATION IN A FLOCK OF DOMESTIC HENS

By Dr. G. McBRIDE and J. W. JAMES*
Department of Animal Husbandry, University of Queensland, Brisbane
AND
Prof. R. N. SHOFFNER
Department of Poultry Science, University of Minnesota, St. Paul

It has been known for some time that animals do not space themselves at random under high density conditions; for example, Hediger's[1] concept of "specific individual distance" between animals in a group is based on the observation that there is a minimum distance below which animals do not approach one another.

Observations on domestic poultry suggested that the factor involved in this spacing tendency was visual and associated with the relative positions of other faces in the vicinity. Such a hypothesis could be tested by the analysis of head positions of poultry from photographs.

A stable flock of 750 Australorp × White Leghorn females 10 months of age housed intensively on deep litter in a shed 100 ft. × 30 ft. was used in this investigation. Photographs were taken from above by a hidden observer without regard to the content of the photographic field, which was 7·5 ft. × 5 ft., an area of about 38 sq. ft. To vary the number of birds per photograph the birds were then crowded into $\frac{1}{2}$ and then $\frac{1}{4}$ of the total area, and in all 24 usable photographs were obtained, with from 5–17 birds per photograph.

---

* Present address: School of Wool Technology, University of New South Wales, Sydney.

Two hypotheses were tested from these photographs: (1) Is the distribution of head locations random? (2) Are the heads randomly oriented?

The method of Clark and Evans[2] was used to test randomness of head locations. This method uses the distance to nearest neighbour of each bird to calculate a coefficient, R, which varies from zero (extreme clumping) to 2·15 (perfectly uniform spacing) with an expectation of 1·0 when spacing is random.

The second hypothesis is that the orientation of the head of every bird depends on the proximity and orientation of the heads of its neighbours. Any neighbour may influence a bird directly or through its effect on another neighbour. A simple model for testing direct effects of neighbours is the partial regression equation:

$$Y = b_1X_1 + b_2X_2$$

where Y, X_1 and X_2 are as defined in Fig. 1, and b_1 and b_2 measure the independent effects on Y of X_1 and X_2 respectively.

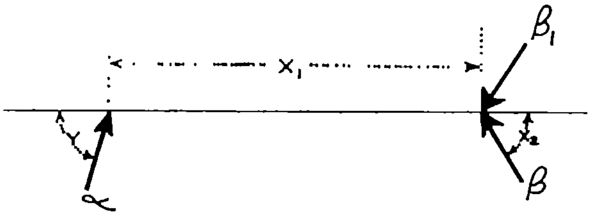

Fig. 1. The arrows represent the position of heads of fowls α, β and β_1. β is the nearest neighbour of α and their head angles to face each other are Y and X_2. The distance between them is X_1.

It can be seen from Fig. 1 that birds β and β_1 each have the same X_2 angle. Since these may be different social situations, β_1 is classed as 'opposite' and β as 'same' side angles. Separate analyses were made for each situation to determine whether they gave rise to different regressions.

The regressions were calculated for nearest, second nearest and third nearest neighbours, on the assumption that nearest neighbours would exert the strongest influence.

Birds around the edges of the photograph were included in the analyses although their correct ranking neighbours may not have appeared on the photograph. The errors introduced by this procedure are unknown, but would lower the apparent significance of the regressions obtained, if indeed real relationships were present.

(1) *Distribution of Head Locations.* Twenty-four photographs (239 birds) were analysed; an average R value of 1·259 ± 0·0110 was obtained. This represents a very highly significant ($P < 0\cdot001$) deviation from randomness, indicating that birds' heads tend to be somewhat evenly spaced throughout the pen.

(2) *Influences on Head Orientation.* (*a*) ***First, second and third nearest neighbours.*** Partial regression coefficients, b_1 and b_2 for first, second and third nearest neighbours were calculated for each of the 24 photographs, the results being summarized in Table 1.

Table 1. MEAN VALUES OF b_1, b_2 AND THE POOLED (WITHIN ANALYSIS) PROPORTION OF VARIANCE DUE TO REGRESSION (r^2) FOR FIRST, SECOND AND THIRD NEIGHBOURS

	Neighbours First	Second	Third
b_1 (degrees/ft.)	23·1 ± 7·8**	10·8 ± 7·9	1·9 ± 10·3
b_2 (degrees/degrees)	−0·326 ± 0·063***	−0·113 ± 0·079	−0·217 ± 0·109*
r^2	0·336 (F = 1·76*)	0·254 (F = 1·19)	0·224 (F = 1·01)

Table 1 shows clearly not only the magnitude of the effects found but also that the relationships are mainly concerned with nearest neighbour, though there may be some effect of other near neighbours.

(*b*) *Nearest Neighbour Analyses.* The mean b_1 and b_2 values for 'same' and 'opposite' sides are as follows:

b_1 (same) = 50·5 ± 30·8, b_1 (opposite) = 44·9 ± 41·32
b_2 (same) = −0·35 ± 0·12, b_2 (opposite) = −0·42 ± 0·27

The statistical differences between the two situations are not significant, so that social differences are probably also negligible, if present. The division into two classes reduced the degrees of freedom per analysis, and raised the standard errors very considerably.

The effect of the proximity of the nearest neighbour is clearly established (b_1, Table 1). For any constant head angle of its nearest neighbour, a bird turned 23° to face that neighbour as the latter approached one foot, and turned away as the neighbour retreated. The regression measures the linear or average component of this movement, but it is not possible to say whether in fact the effect is the same over all ranges of distance.

The correlation between X_1 and X_2 was calculated for each photograph and an average value of 0·239 ± 0·084** was found. Thus its nearest neighbour also turned towards each bird as the distance between them decreased. The general picture is, then, that as two birds approach each other, they also face each other more directly. This motion appears from observations to be defensive.

On the other hand, the average b_2 value for nearest neighbours was negative and highly significant (b_2, Table 1). This means that at any constant distance between neighbours they tend to avoid each other's frontal aspect. Once again this is an average effect.

When the pooled within photograph partial regression equation was calculated the following results were found: $b_1 = 22\cdot9 \pm 4\cdot8^{***}$; $b_2 = -0\cdot130 \pm 0\cdot063^{*}$. The agreement with the average value is good for b_1, but not nearly so good for b_2. This suggests that the b_2 values for separate photographs are heterogeneous. One factor likely to be responsible, density, was examined. The regression of b_2 on number of birds per photograph (N) was:

$$\hat{b}_2 = -1\cdot338 + 0\cdot103\,N \ (P \simeq 0\cdot10)$$

where $\hat{b}_2$ is the estimated value of b_2 from this regression. This regression, though not significant, may be a partial explanation of the heterogeneity of b_2 values. If genuine, this relation would mean that at high densities the hens show less tendency to avoid each other's frontal aspect, which is consistent with the finding earlier, that as the distance between neighbours diminishes, they tend to face each other. Alternatively, it could be suggested that at higher densities the presence of many birds in the immediate vicinity may make it impossible for the hen to avoid simultaneously the faces of its neighbours.

Discussion and Summary

Evidence has thus been presented to show that hens do not arrange themselves at random under normal intensive housing conditions. The spacing of the heads is more regular than it would be under random spacing. This regularity is probably based on visual interactions with neighbouring birds. As a neighbour approaches, a bird tends to turn to face it. Nevertheless, they tend to avoid each other's frontal aspect in so far as this is compatible with the tendency already mentioned. There was slight, but not significant evidence that this latter tendency decreased as density increased. Second and third nearest neighbours had less effect than did nearest neighbours.

It seems clear from this evidence that the presence of a bird's head constitutes a social force on its neighbours. The word 'force' is here used to mean that there is a measurable effect on behaviour of neighbours.

This force diminishes with distance and is maximum directly in front of the head. A possible analogy is to compare this force with the fields of magnetic force associated with a single pole of a magnet.

The movements of birds in such a field of forces are not at random—they maintain their heads at a regular pattern of spacing and orientate them to avoid the frontal aspects of other birds, yet turn, probably defensively, to face neighbours who approach closely.

RIBONUCLEOPROTEINS IN LEAVES INFECTED WITH TOBACCO MOSAIC VIRUS

By P. M. TOWNSLEY

Research Station, Canada Department of Agriculture, 6660 N.W. Marine Drive, Vancouver, B.C.

THE presence of at least two proteins characteristic of tobacco mosaic virus (TMV) infection were demonstrated by introducing amino-acids labelled with carbon-14 to sections of diseased tobacco leaves in nutrient solutions. These proteins were detected using agar-gel electrophoresis[1,2]. Anomalous ribonucleoproteins in the supernatant fluids after ultracentrifuging extracts of diseased plants were noted by Bawden and Pirie in 1956 (ref. 3) and by Dupont-Mairesse and Jeener in 1960 (ref. 4). The former purified their preparations by hydrogen ion and salt fractionation and the latter by a precipitin reaction. This investigation reports on the separation of ribonucleoproteins related to TMV by agar-gel electrophoresis and describes some of their biochemical properties.

A common strain of TMV was purified by passage through the local lesion host *Nicotiana glutinosa* L. and then returned to seedlings of the systemic host *Nicotiana tabacum* L. var. Haronova from which leaf samples were later taken for this investigation. Components of extracts from the resulting diseased plants were separated by agar-gel electrophoresis. The infectivity of the virus preparations was assayed quantitatively using *N. glutinosa*.

Serologically related fractions were located within the agar gel by immunoelectrophoresis[5]. The following procedure was used to prepare antibody against TMV. Leaves of TMV diseased *N. tabacum* were frozen overnight, thawed and ground and the extracted juice adjusted to *p*H 7·2 with potassium phosphate. The juice was submitted to two cycles of differential centrifugation at 78,000*g* for 90 min and 2,000*g* for 15 min. The resulting pellet was dialysed against physiological saline. The antigen was injected into rabbits. (The TMV antiserum was supplied by Dr. N. S. Wright.)

Uniformly labelled L-leucine-^{14}C was obtained from the Biochemical Centre, Amersham, England, and radioactive orthophosphate was obtained from Atomic Energy of Canada, Ltd. Radioactivity was measured with a Nuclear-Chicago *D*47 gas flow Geiger tube. The relative amount of radioactive leucine and phosphate incorporated into the same sample was determined by measuring the total disintegration and the disintegration of phosphate. The radioactivity rate of the phosphate was obtained by placing a piece of celluloid at a defined distance between the Geiger tube and the sample. The celluloid absorber reduced the radioactive carbon detection by 99·8 per cent and the phosphate detection by 23·1 per cent.

When the agar was dried by flowing dry air over one side of the agar sheet, the particles within the gel diffused to the surface forming an infinitely thin layer. After removing the buffer salts the radioactivity of this thin layer was measured directly.

The term 'soluble antigen' as used in this investigation was that phosphorus-free soluble protein serologically related to TMV (ref. 6). Tentative identification of this zone was accomplished by co-electrophoresis with a nucleic acid-free preparation of TMV (ref. 7).

A description of the technique for sampling the agar gel for electron microscopy has been published[8]. Electron micrographs were kindly taken by a colleague, Dr. M. Weintraub.

(*a*) *Agar-gel fractionation of crude TMV plant extracts.* Earlier work on crude diseased plant extracts on agar gel revealed a number of fractions peculiar to the disease[2]. The so-called 'fast' band was probably the most readily detectable fraction apart from the band of non-aggregated TMV. Following the TMV band were other bands associated with the disease in addition to bands formed by aggregated TMV particles.

From the results of many experiments on crude TMV extracts at various intervals following infection of the host and on diseased hosts grown under a variety of conditions, it was concluded that the concentration of the fast band relative to the TMV band was variable. When the TMV diseased host, *N. tabacum*, was placed in unfavourable conditions of growth, the concentration of the fast band was greatly augmented. Concentration of the fast band was much greater from infected leaf disks than from an infected, intact, vigorous host plant.

(*b*) *Immunoelectrophoresis of crude TMV plant extracts.* After fractionation of the crude extracts by electrophoresis, at least four areas within the agar were serologically related to TMV (Fig. 1). Since serological activity in agar gels can be observed only by visible precipitin reactions, there may be other serologically related areas which were not detected. The precipitin reaction within the gel appeared to be the same for the area near the origin and the TMV band. These areas gave a narrow but strong reaction. The serologically related areas running before and behind the TMV band were rather diffuse faint broad areas extending out from the TMV band. No precipitin reaction could be detected by using the same TMV antiserum against healthy extracts nor extracts of plant tissue infected with potato *X* virus.

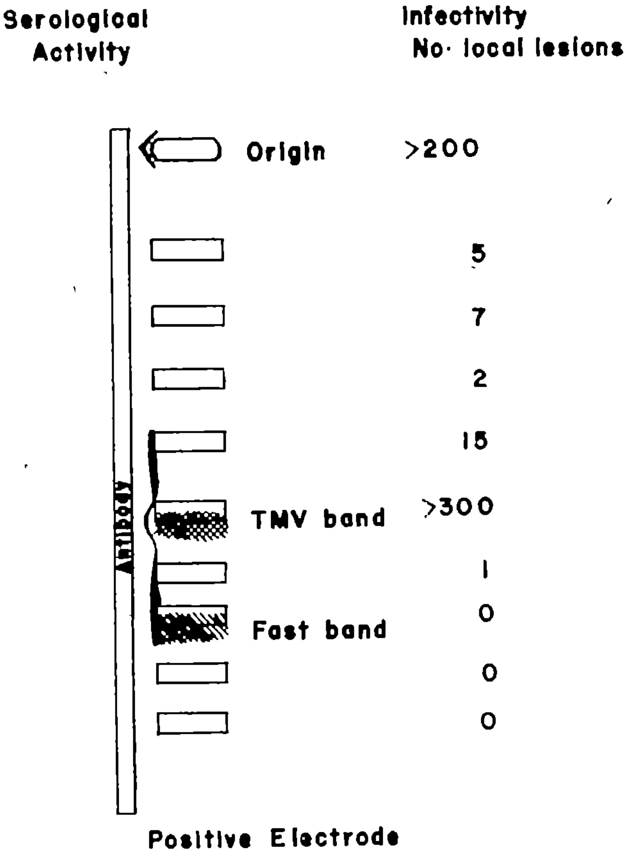

Fig. 1. Location of serological activity and infectivity of a crude TMV plant extract after agar gel electrophoresis

---

* Present address: Fisheries Research Board of Canada, Halifax, Nova Scotia.

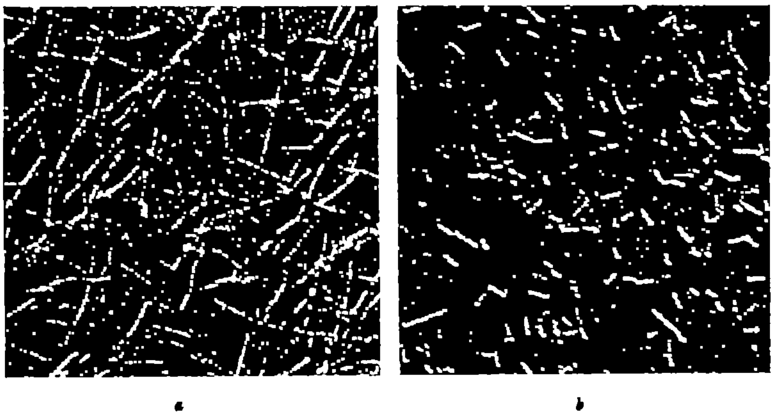

Fig. 2. Electron micrographs of material from the (*a*) TMV band and (*b*) fast band of a crude TMV plant extract after agar-gel electrophoresis (shadowed with palladium; × *c*. 13,300)

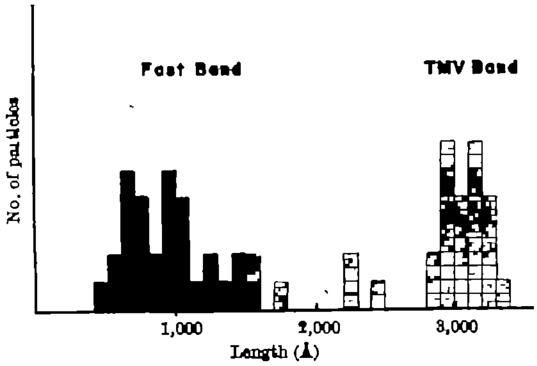

Fig. 3. Size distribution of particles from the TMV band and fast band from Fig. 2 (black and shaded) indicate the size of the particles found in the electron micrographs of the fast band and the TMV band respectively

(*c*) *Location of infectivity within agar gels*. The infectivity of various locations within the agar gels was determined by crushing samples of agar from these areas over the leaf surface of the local lesion host, *N. glutinosa*. The results of such an experiment are shown in combination with serological activity in Fig. 1.

Several experiments indicated that there may be comparatively low infectivity within the fast band in an area nearest to the TMV band. Infectivity was never observed in the distal areas of the fast band. A high proportion of the infectivity did not migrate from the origin and low infectivity was detected scattered between the origin and the TMV band.

(*d*) *Electron microscopy*. Electron microscopy of TMV preparations fractionated by agar-gel electrophoresis was rewarding. From a crude preparation, electrophoresis fractionated the sap according to size, charge on the particle, and adsorption on agar gel[8,9]. Thus, the preparations for electron microscopy were exceptionally free of debris, containing particles characteristic of a particular zone. Electron micrographs of the TMV band and the fast bands are shown in Fig. 2. Size distribution is shown in Fig. 3.

(*e*) *Radioactive isotope studies*. Labelled orthophosphate and amino-acids can be incorporated into TMV (refs. 2 and 10) in amounts that can be measured easily by determining the radioactivity in the dried gels. Fig. 4 shows the rate of incorporation of orthophosphate and leucine into TMV in 2- to 3-mm leaf squares. Two observations appear interesting: leucine-^{14}C is detected in the TMV particle earlier than orthophosphate; the curve for isotope incorporation into the TMV band is very similar to that of the fast band.

The ratio of leucine-^{14}C incorporated into TMV to leucine-^{14}C incorporated into the fast band increased with time. In the latter experiment the fast band has about half the total radioactivity of the TMV band, but 1/10 the protein as measured by optical density or by staining. (Optical density of the bands within the gel was measured by a continuous scanning apparatus devised by me.) Therefore, the specific radioactivity of the protein in the fast band exceeds that of the TMV band. However, since the newly synthesized virus is diluted with pre-formed virus, the specific activity does not indicate the sequence of formation of the virus nor the other fraction. Whereas the incorporation of leucine into the TMV band and the fast band is of the same type as judged by the curves, the amount of radioactive phosphorus taken up by these two fractions was quite different. This suggested that the nucleic acid in these two fractions was at least in part dynamically different. Probably a large

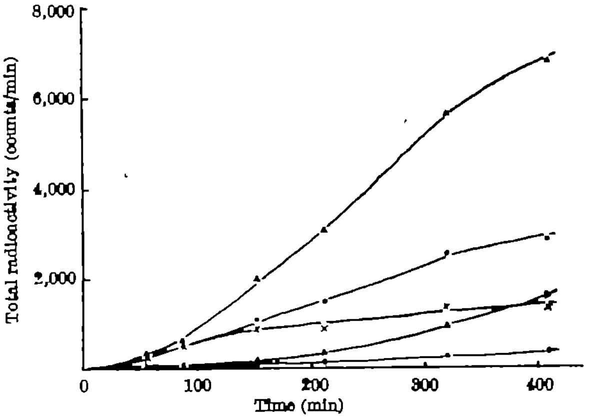

Fig. 4. Rate of orthophosphate and leucine incorporation into the TMV band, the fast band, and the soluble antigen. 2–3 mm leaf squares from plants suffering from severe mosaic and light green in colour (pot bound) were placed in Hoagland's solution (ref. 1) containing 10 μc. of uniformly labelled leucine-^{14}C and 100 μc. of orthophosphate-^{32}P. Samples were removed at time intervals and the plant juice separated by electrophoresis (ref. 1)

▲, TMV band leucine-^{14}C; ●, fast band leucine-^{14}C; ×, soluble antigen leucine-^{14}C; Δ, TMV band orthophosphate-^{32}P; ○, fast band orthophosphate-^{32}P

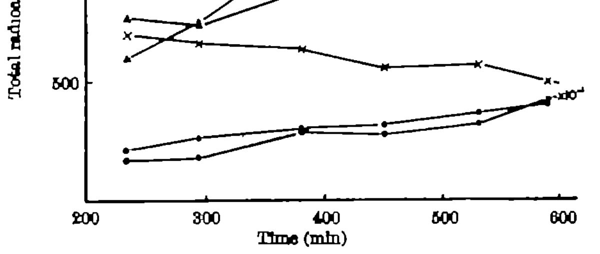

Fig. 5. Rate of orthophosphate and leucine depletion in the TMV band, the fast band and the 'soluble antigen'. 2–3-mm leaf squares from plants suffering from severe mosaic were placed in distilled water for 20 h under artificial light. The distilled water was replaced with Hoagland's solution containing 10 μc. of uniformly labelled leucine-^{14}C and 100 μc. of orthophosphate-^{32}P. After 60 min, the leaf tissue was washed four times with distilled water followed by three washings with Hoagland's solution containing the non-radioactive substrate (0·14 g/l. KH_2PO_4 and 0·1 g/l. of L-leucine). The leaf tissue was placed in the latter non-radioactive substrate and samples removed at time intervals for extraction and electrophoresis. The symbols are the same as in Fig. 4

part of the radioactive phosphorus of TMV was derived from *in vitro* incorporation as previously described[11]. The leucine-^{14}C content of the 'soluble antigen' behaved as if this fraction was transient. No radioactive phosphate was located in the 'soluble antigen' area.

In order to determine whether the radioactivity of some fractions was transitory, the diseased leaf sections were permitted to take up radioactivity for a short period, washed to remove extra-cellular radioactivity and then incubated in non-radioactive substrate for given times (Fig. 5). It was seen that the fraction corresponding to the soluble antigen was the only one which lost total radioactivity suggesting that the soluble antigen itself was transitory. Radioactivity in the fast band and the TMV band increased during the experiment. It was decided that leaf disks or sections were unsatisfactory for this type of experiment because of the long time required to deplete the tissue of radioactivity.

From these experiments it is readily seen that electrophoresis of TMV preparations in agar gels provides a valuable analytical tool for biochemical investigations. From a single small sample fractionated by agar-gel electrophoresis it was possible to obtain data on size, electrophoretic mobility, infectivity, ratio of incorporation, concentration and serological activity.

It has been shown by me[10] and recently by Dupont-Mairesse and Jeener[4] that nucleic acid may be incorporated into or associated with the virus or virus protein during extraction of the virus from the diseased leaf, but whether this is merely association or a demonstration of synthesis remains to be proved. The fast band described here is consistently found in TMV preparations isolated by centrifugation at 78,000*g* for 90 min. The band does not appear to be a degradation product of the virus because there is higher specific activity of the protein portion and the concentration of the fast band is independent of the concentration of the TMV band. If the particles of the fast band are on the path to synthesis of the virus then it could be assumed that the nucleic acid within this protein would also be found as a constituent of the typical virus particle. But the rate of isotopic enrichment in these particles is different from that of the finished virus particles. Therefore the mature virus particle could not be synthesized by linear polymerization of the material of the fast band unless the additional phosphate radiation found in the mature virus is added at this time. Thus it is conceivable but not proved here that the virus protein of the fast band could have the role of selectively gathering specific ribose polynucleotides of the cell the composition of which would not resemble the typical virus nucleic acid until a final synthetic step.

ORIGIN OF METHYL KETONES FOUND IN STEAM DISTILLATES OF MILK FAT

By R. C. LAWRENCE and J. C. HAWKE

Dairy Research Institute and Massey University College, Palmerston North, New Zealand

It has recently been suggested by Boldingh and Taylor[1] that the homologous series of methyl ketones with an odd number of carbon atoms from C_7 to C_{15}, obtained by steam distillation of milk fat at 180° C, is formed from β-keto-acids. Their experiments indicated that β-keto-acids are present in bound form as triglyceride components in milk fat. Investigations in progress when Boldingh and Taylor's report[1] appeared have shown that very similar quantities and relative proportions of the same homologous series of methyl ketones are formed as artefacts during the steam distillation of butterfat at 100° C. Exhaustive distillation indicated that only limited quantities of the methyl ketones could be obtained from milk fat and that the precursors were thus present in relatively small amounts[2].

In an attempt to confirm that the β-keto-acids (or other precursors of these methyl ketones) were intermediates in fatty acid synthesis, milk fat was obtained from a cow which had been milked 9 and 22 h after the intravenous injection of [carboxy-^{14}C]-acetate (5 mc.). 15 g of a composite sample of the milk fat from the two milkings were then exhaustively steam distilled at 100° C, the distillate (10 l.) being led directly into 2,4-dinitrophenylhydrazine reagent. The distillate and reagent mixture were held at room temperature for 48 h, the 2,4-dinitrophenylhydrazones extracted and separated by column partition chromatography[3]. The fractions were identified, and their purity established, by paper chromatography[4,5]. The concentrations of methyl ketones were determined spectrophotometrically as the 2,4-dinitrophenylhydrazones at 362 mμ. In addition to the homologous series of methyl ketones from C_3 to C_{15} with odd numbers of carbon atoms, small amounts of butan-2-one were also isolated (Table 1).

To determine specific activities, suitable aliquots of each of the 2,4-dinitrophenylhydrazones were dissolved in 5 ml. scintillation fluid (0·5 per cent 2,5 diphenyloxazole + 0·03 per cent 1,4-di-[2-(5-phenyloxazolyl)]-benzene in toluene) and counted at room temperature in a liquid scintillation system (*NE* 8301; Nuclear Enterprises (G.B.), Ltd., Edinburgh). Corrections for quenching by the 2,4-dinitrophenylhydrazones were established by the use of *n*-hexadecane labelled with carbon-14 as an internal standard. The specific activities of the isolated 2,4-dinitrophenylhydrazones, corrected for quenching, showed that C_9, C_{11}, C_{13} and C_{15} methyl ketones exhibited the highest activities (Table 1).

Table 1. DISTRIBUTION OF RADIOACTIVITY IN METHYL KETONES OBTAINED BY EXHAUSTIVE STEAM DISTILLATION AT 100° C OF MILK FAT FROM A COW AFTER INTRAVENOUS INJECTION OF [CARBOXY-^{14}C]-ACETATE

Methyl ketone	mg/kg milk fat	Moles as per cent of total	Specific activity/ mg C*	Per cent of total radioactivity
C_{15}	51	11·8	5,820	13·7
C_{13}	28	7·4	9,800	23·3
C_{11}	15	4·6	19,170	45·2
C_9	20	7·4	4,290	10·1
C_7	28	12·8	1,690	4·0
C_5	16	9·7	270	0·6
C_4	8	5·8	1,300	3·1
C_3	45	40·5	—	—

* Methyl ketones counted as 2,4-dinitrophenylhydrazones and corrected for quenching.

This was confirmed qualitatively by preparing autoradiographs of the paper chromatograms used to separate and identify the 2,4-dinitrophenylhydrazones. No radioactivity was detected in the 2,4-dinitrophenylhydrazone of acetone but the excessive quenching in this instance made it difficult to establish the accuracy of this observation. In an attempt to overcome quenching, the methyl ketones from C_7 to C_{15}, which had been shown to possess a large

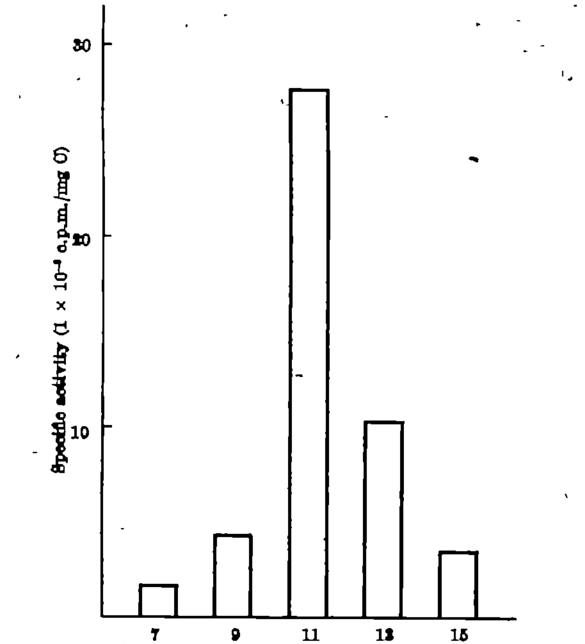

Fig. 1. Relationship between specific activity and chain length of methyl ketones found in steam distillates of milk fat from a cow intravenously injected with 5 mc. of [carboxy-^{14}C]-acetate. Methyl ketones were regenerated from the corresponding 2,4-dinitrophenylhydrazones

proportion of the total radioactivity, were regenerated from the corresponding 2,4-diphenylhydrazones with lævulinic acid[6] and counted as here. Much less quenching was encountered and the correction factors needed, as determined by the use of ^{14}C-*n*-hexadecane, were correspondingly smaller. The specific activities obtained by this method (Fig. 1) were, with the exception of the increased activity of C_{11}, almost identical to the activities determined from the 2,4-dinitrophenylhydrazones directly.

There is a marked similarity between the carbon-14 labelling pattern of these methyl ketones and the fatty acids isolated by Popják, French, Hunter and Martin[7] from a composite sample of milk fat obtained 1–12 h after the intravenous injection of a lactating goat with [carboxy-^{14}C]-acetate. Although the C_{11} methyl ketone and the C_{12} fatty acid possessed the maximum activities in the respective experiments, the activities fell away on either side of these maxima in like manner. Some differences in labelling pattern are to be expected since the milk fat in the present investigation was obtained from a cow milked 9 and 22 h after injection. In another experiment Gerson, Hawke, Shorland and Melhuish[8], using milk fat from a cow into which ^{14}C-valerate had been injected intravenously, found two maxima of specific activity, one at C_{12} for the fatty acids C_{10}–C_{16} and the other at C_4 for the range C_2–C_8. More significantly Popják *et al.*[7] found that fatty acids of higher molecular weight than palmitic acid possessed very little radioactivity and in the present investigation no heptadecan-2-one could be detected in any of the distillates, despite the relatively large amounts of C_{18} acids in milk fat.

The generally accepted view is that, in the biosynthesis of milk fat[9–11] and other lipids[12], the fatty acids up to and including palmitic are synthesized from an acetate pool whereas C_{18} acids and above are synthesized by less direct pathways or from the blood lipids. The agreement in the specific activity patterns of the methyl ketones found in steam distillates of milk fat and the corresponding fatty acids with one more carbon atom would appear to justify the conclusion that both have common precursors such as β-keto-acids. It is conceivable that trace amounts of such precursors, intermediates in fatty acid synthesis from acetate in the mammary gland, escape normal reduction to the corresponding fatty acid and become incorporated in the triglyceride molecule of milk fat.

We gratefully acknowledge the gift of radioactive butterfat from Mr. T. Gerson, Fats Research Laboratory, Wellington.

EFFECT OF PUROMYCIN ON THE REPLICATION OF WESTERN EQUINE ENCEPHALITIS AND POLIOMYELITIS VIRUSES

By Dr. EBERHARD WECKER
Wistar Institute of Anatomy and Biology, Philadelphia, Pa.

IN previous work we have described the effect of two amino-acid analogues on the replication of Western equine encephalitis virus (WEE)[1] and poliovirus[2]. *Para*-fluorophenylalanine (FPA) was shown to reduce cellular protein synthesis if used at sufficiently high concentrations[1]. Under these conditions FPA also inhibited the appearance of infectious viral RNA and viral antigens[3]. In contrast, FPA at low concentrations did not inhibit the synthesis of protein in the infected cell nor did it inhibit the formation of infectious RNA of WEE and poliovirus[2,3]. However, no infectious virus was formed, and it was found that this was most likely due to the incorporation of the amino-acid analogue into viral proteins (ref. 3, cf. ref. 5). Another amino-acid analogue—ethionine—which is always incorporated and even at high concentrations does not inhibit protein synthesis significantly produced effects on WEE virus formation similar to those of FPA at low concentrations[4]. Thus it was suggested that the synthesis of aberrant proteins due to the incorporation of amino-acid analogues is still compatible with the proper formation or preservation of infectious viral RNA (ref. 5). On the other hand, any substance which actually inhibits the mechanism of protein synthesis, such as FPA at high concentrations, might be expected to interfere with the appearance of infectious RNA in the cell.

Because puromycin is a powerful inhibitor of protein synthesis (cf. refs. 3 and 5) and has a mechanism of action supposedly quite different from that of amino-acid analogues[6,7], its effect on the appearance of infectious RNA of WEE and polio was examined. Fig. 1 shows the dose response curves to puromycin of virus maturation and appearance of infectious RNA in the case of WEE. Virus maturation is more sensitive to the inhibitor than the synthesis of infectious RNA, although the differences are somewhat less pronounced than with FPA (ref. 2).

Puromycin at 7·5 μg/ml. can also inhibit completely the appearance of infectious polio RNA in HeLa cells (Fig. 2). At this concentration the incorporation of lysine-^{14}C into cellular proteins is drastically inhibited (Fig. 3). By simply removing the inhibitor from the infected cultures, the infectious RNA accumulated in the cells at a rate which was identical to that of the controls. This is demon-

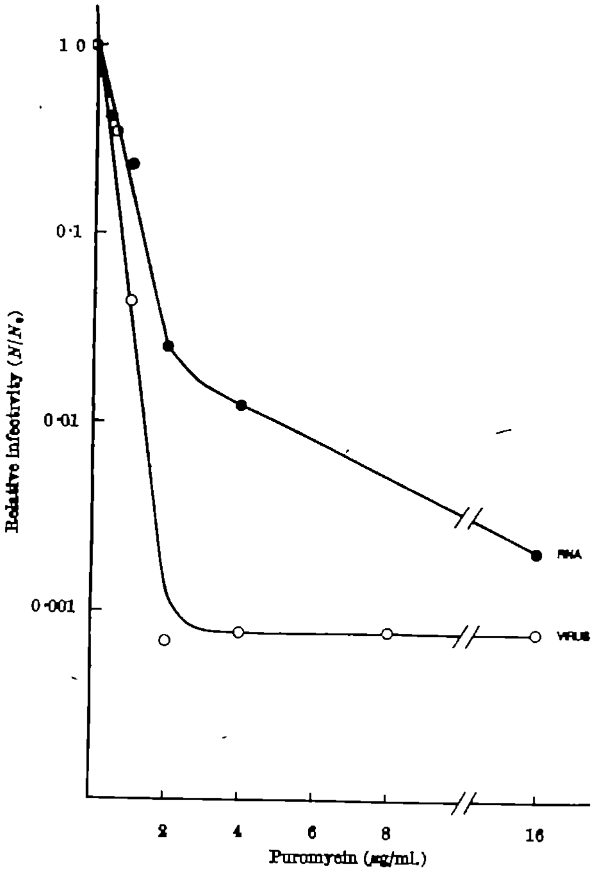

Fig. 1. Dose response of the formation of WHE virus and infectious RNA to puromycin. The infected cells were exposed to the indicated concentrations of puromycin for 5 h. Aliquots of cells were then tested for cell-associated virus (CAV) and cold phenol extractable RNA

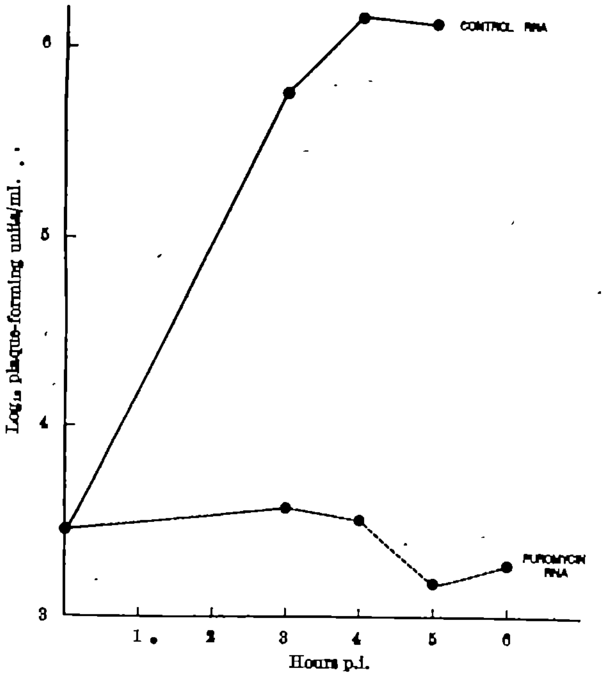

Fig. 2. Inhibition by puromycin of the demonstrable formation of infectious polio RNA. Infected HeLa cells were extracted for infectious polio RNA after various times of incubation. The inhibited cells received 7·5 μg/ml. of puromycin at time 0. Time 0 is the time of re-incubation following 1 h of incubation for virus adsorption

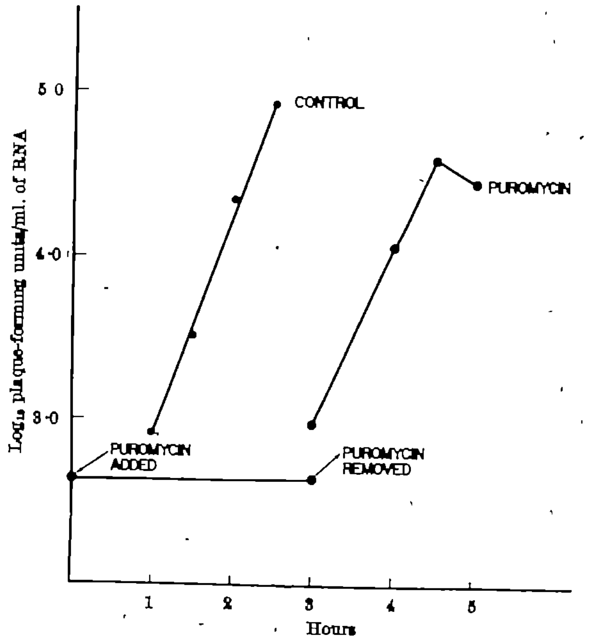

Fig. 4. Onset of polio RNA formation after removal of puromycin. The puromycin-inhibited cells were incubated for 3 h with 7·5 μg/ml. of puromycin following 1 h of virus adsorption. The inhibitor was removed by washing the cells twice with prewarmed phosphate-buffered saline. Prewarmed medium was added and the cells were further incubated for the indicated times

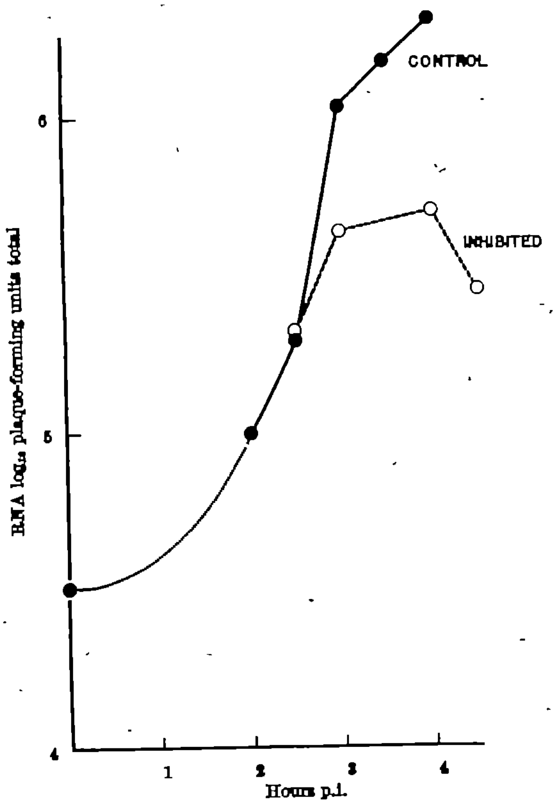

Fig. 5. Interruption of polio RNA formation by puromycin. An aliquot of the infected cells received 15 µg/ml. of puromycin at time 2½ h. Samples of controls and inhibited cells were extracted for infectious RNA at the times indicated

strated in Fig. 4, which also shows that there was no appreciable lag period between removal of the inhibitor and increase of infectious RNA. It would appear, therefore, that the lag period usually observed between infection and the rise of infectious polio RNA is due to mechanisms other than those which are inhibited by puromycin. This is of particular interest with respect to the problem of the requirement for an 'early protein synthesis' before the production of infectious RNA in the case of certain animal viruses. Our results suggest that HeLa cells may replicate polio RNA without the preceding synthesis of novel proteins, for example, enzymes. Such a possibility was already suggested by previous experiments with FPA (refs. 1 and 5) and more recently by results obtained by Wheelock using puromycin in HeLa cells infected with Newcastle disease virus[6]. Other alternatives to this conclusion are: (1) that early proteins are produced within a very short period following removal of the inhibitor; or (2) that the early proteins were formed despite the puromycin which at the concentrations used may still allow some protein synthesis to occur (Fig. 3).

The increase of infectious viral RNA cannot only be prevented but can also be interrupted by puromycin. This is shown in Fig. 5 in the case of poliovirus-infected HeLa cells. Thus, there is strong evidence that the continuing synthesis of a non-enzyme protein is also required for either formation or preservation of infectious polio RNA in HeLa cells. The fact that puromycin, like FPA, halts any additional increase of infectious RNA adds considerably to the previously advanced notion that the protein in question is non-enzymatic in function[1,5]. When FPA is used as an inhibitor, this amino-acid analogue could still permit the synthesis of a theoretical enzyme which is not enzymatically active but is nevertheless able to compete for the substrate sites with active enzymes formed before the addition of FPA. Such competition between active and inactive enzyme molecules of comparable affinity to a given substrate could, of course, drastically reduce or even abolish formation of the end-product of the reaction, that is, the infectious RNA. With puromycin as inhibitor such a mechanism is less feasible because it is likely to either permit the synthesis of functional enzymes or inhibit their synthesis completely. Both puromycin and FPA have now been shown to exert very similar effects on the appearance of infectious RNA. It might therefore be concluded that in either case the protein which is required for the appearance of infectious RNA is not an enzyme but a structural protein, that is, the viral protein[5].

The work was supported in part by a contract with the U.S. Army Chemical Corps Biological Laboratories, Fort Detrick, Maryland, and a grant from the Samuel S. Fels Fund.

PRE-LUMIRHODOPSIN AND THE BLEACHING OF VISUAL PIGMENTS

By TÔRU YOSHIZAWA and GEORGE WALD
Biological Laboratories of Harvard University, Cambridge, Mass.

THE visual pigment rhodopsin is composed of the protein opsin to which is attached as chromophore a hindered *cis* isomer of vitamin A aldehyde, 11-*cis* retinal. (In accordance with recent recommendations of the Committee on Nomenclature of the International Union of Pure and Applied Chemistry, we shall use hereafter the following terminology: for vitamin A, 'retinol'; for vitamin A aldehyde (retinene), 'retinal' or 'retinaldehyde'; for vitamin A acid, 'retinoic acid'.) Rhodopsin bleaches in the light over a series of transient, highly coloured intermediates to an eventual mixture of opsin and all-*trans* retinal[1].

Some years ago, by irradiating rhodopsin at −50° to −100° C, we obtained what we thought to be the first such intermediate, called lumirhodopsin. On warming to about −20° in the dark, lumirhodopsin yielded a second intermediate, metarhodopsin; and on further warming and with access to water this hydrolysed to the final mixture of all-*trans* retinal and opsin[2].

Hubbard and Kropf analysed these processes further[3]. Free retinal in solution is isomerized by those wave-lengths of light that it absorbs to an eventual steady-state mixture of all possible *cis* and *trans* isomers[1]. Light acts in the same way on the retinal attached as chromophore in a visual pigment. The absorption of a first photon by rhodopsin, for example, activates the isomerization of its 11-*cis* chromophore to all-*trans*. The absorption of a second photon produces a new electronically excited state, from which the molecule may emerge all-*trans* or in any of its mono*cis* configurations. Long-continued irradiation at $-50°$ to $-100°$ consequently ends in a steady-state mixture of isomers, still attached to opsin. In this final mixture, the 11-*cis* fraction is rhodopsin; the 9-*cis* fraction is isorhodopsin[1]; the all-*trans* fraction, with perhaps a representation of other *cis* isomers, is lumirhodopsin. On warming in the dark, the lumirhodopsin bleaches over metarhodopsin to retinal and opsin; the rhodopsin and isorhodopsin, which are stable in the dark, remain as residues. The change from lumi- to meta-rhodopsin involves a rearrangement of the protein structure.

A few years ago Yoshizawa *et al.* at Osaka University began to obtain evidence that the irradiation of rhodopsin at liquid nitrogen temperature ($-195°$ C) yields an earlier product than lumirhodopsin[4]. Constraints of equipment limited these workers to indirect measurements, which showed, however, that the new intermediate is developed maximally by irradiating at $-195°$ with light of short wave-lengths (440 mμ), and that it reverts almost completely to rhodopsin on re-irradiating with light of wave-length 612 mμ at the same temperature[5]. The absorption spectrum of the new intermediate must therefore lie far toward the red from that of rhodopsin, which scarcely absorbs light at 612 mμ. This intermediate was shown to be stable to about $-140°$, above which it forms lumirhodopsin[6]. We shall call it pre-lumirhodopsin.

Grellmann, Livingston and Pratt at the University of Minnesota have recently examined the new intermediate in solutions and suspensions of rod outer segments, and have studied the kinetics of its decay to lumirhodopsin[7].

The present investigation confirms Yoshizawa's earlier observations by direct low-temperature spectrophotometry, and goes on to analyse the status of pre-lumirhodopsin in the chain of intermediates involved in the bleaching of rhodopsin and isorhodopsin.

Methods

All measurements were made with the Cary 11 recording spectrophotometer. The absorption vessel was modified from one for which we are indebted to Dr. W. B. Gratzer[8], in which a cold finger, filled with liquid nitrogen, ends in a copper block which holds the preparation. All this is enclosed within a glass jacket, the space between the cold finger holding the preparation and the jacket being continuously evacuated. For further insulation the cell is embedded in a block of 'Styrofoam', the light path being closed at the ends with plane quartz windows. The rhodopsin solutions, in 2 per cent aqueous digitonin, were mixed with various proportions of glycerol. In the absorption vessel they form a film about 0·8 mm thick between a front quartz plate and a back opal glass plate, held in the copper block with screw-on rings. A similar plate of opal glass is placed in the comparison beam. The temperature is measured continuously with an iron–constantan thermocouple inserted in the copper block. Pouring liquid nitrogen in the cold finger brings the temperature of the pigment solution close to $-195°$. Other temperatures are obtained by allowing the system slowly to warm. At temperatures below about $-50°$, the glycerol–water mixtures form a glass. Below about $-100°$, this cracks and crazes to various degrees. The resultant scattering of light is swamped by the opal glass window directly behind the pigment solution. Before measuring each spectrum the recording pen is arbitrarily zeroed at 700–750 mμ, a wave-length range in which none of these pigments absorbs appreciably.

Measurements

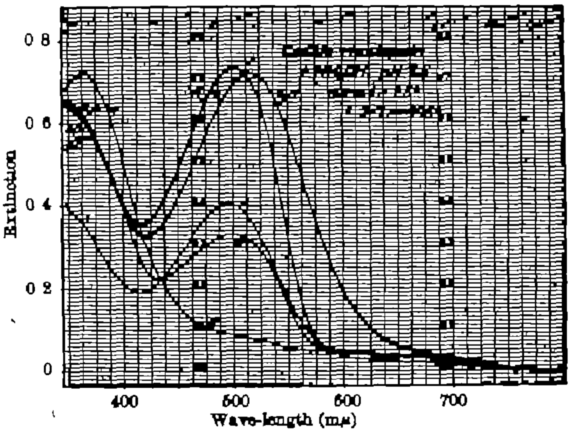

Fig. 1. Cattle rhodopsin in a glycerol–water mixture (55 : 45) containing 0·1 M hydroxylamine, at pH 7·5. The spectrum was recorded at room temperature (1), and again in the vitrified solvent at liquid nitrogen temperature (2). Long irradiation at 440 mμ displaces the spectrum to (3), representing a steady-state mixture of rhodopsin and pre-lumirhodopsin. Re-irradiation at 600 mμ brings the spectrum back to (4); the pre-lumirhodopsin has been reconverted to rhodopsin, accompanied by a trace of isorhodopsin. Re-irradiation at 440 mμ restores the steady-state mixture of rhodopsin and pre-lumirhodopsin (5). Pre-lumirhodopsin and rhodopsin are therefore perfectly interconvertible by light at this temperature. The preparation was warmed to 25°, its spectrum measured, and then re-cooled to $-195°$ (6). Then it was re-warmed to 25°, and completely bleached in the light to all-*trans* retinal and opsin, the retinal combining with hydroxylamine to yield retinaldehyde oxime (λ_{max} 367 mμ). On re-cooling to $-195°$ this yielded curve (7). Since retinaldehyde oxime does not absorb light above 450 mμ, curve (7) at higher wave-lengths represents impurities and scattering. Subtracting this from the other curves yields the corrected absorption spectra shown at the left in Fig. 2

Absorption spectrum. On cooling rhodopsin in glycerol–water mixtures from room temperature to $-195°$, its extinction rises 1·70 ± 0·11 times (average of 11 measurements) (Fig. 1, curves 1–2). On this degree of cooling the solvent contracts, by our estimate 7·7 per cent in 67 per cent glycerol and 6·5 per cent in 50 per cent glycerol; so that the rise of extinction corrected for volume contraction is about 1·58. Simultaneously λ_{max} moves from 498 to about 505 mμ.

The absorption band is also sharpened, its long-wave-length limb falling to zero more abruptly than in the warm (cf. rhodopsin, Fig. 2; isorhodopsin, Fig. 7). This is a general phenomenon, owing to the fact that at $-195°$ all the molecules are in the zero vibrational state, and all transitions to the first electronically excited state on absorbing a photon jump off from this single ground-level; whereas in the warm a small fraction of the molecules occupy higher vibrational states, from which transitions to the electronically excited state involve smaller energies, that is, longer wave-lengths of absorption. Hence the absorption bands in the warm end in an attenuated, long wave-length tail, which is lost at low temperatures.

The displacement of spectrum to longer wave-lengths on cooling, though characteristic of the visual pigments and free carotenoids[9], is opposite in direction to the shift observed in porphyrin derivatives, notably chlorophylls and hæm proteins, the spectra of which shift toward the blue on cooling[10]. The long wave-length absorption bands of all such molecules represent electronic transitions from the ground to the first excited state, on which are superimposed a variety of overlapping rotation-vibration changes. Cooling, by altering the relative probabilities of vibrational changes, might displace the 'centre of gravity' of the composite band in either direction; yet the likelier result is a displacement toward the blue, as observed with porphyrin derivatives, since cooling eliminates higher vibrational levels in the ground state, thus making for longer transitions. The contrary behaviour of the carotenoids and their derivatives is probably associated with the fact that carotenoid spectra in the warm lie at 'abnormally' short wave-lengths, owing to steric hindrance between the ring and side-chain[11] and—in various *cis* forms—also between —H and in some cases —H and —CH$_3$ groups along the chain[12]. Such hindrances interfere with conjugation and hence with resonance, and tend to displace the spectrum towards shorter wave-lengths. Cooling apparently relieves such steric hindrances, so permitting more effective conjugation, and shifting the spectrum towards the red.

It is tempting to relate the large rise of extinction of rhodopsin on cooling to the same cause. All-*trans* and the relatively unhindered *cis* isomers of retinal rise in extinction only about 10 per cent on cooling to − 195°; whereas the highly hindered 11-*cis* retinal, owing to the relief of steric hindrance on cooling, rises in extinction 1·63 times[9], as does rhodopsin in the present experiments. It should be noted, however, that isorhodopsin, which possesses as chromophore the relatively unhindered 9-*cis* retinal, rises in extinction about the same amount on cooling to − 195°, so that the large rise of extinction on cooling both these pigments cannot without qualification be ascribed to steric hindrances intrinsic to the free chromophore. It is possible that the attachment to opsin introduces distortions of chromophore configuration that are relieved by cooling, quite apart from what distortions may be present in the free retinals.

As already noted here, below −100° our glycerol–water solutions craze to various degrees, though when cooled as rapidly as in these experiments they seem to remain otherwise clear (that is, non-opalescent). The rises of extinction we observe therefore are not as reliable as if measured in wholly clear media, yet there is no present reason to believe that they involve large errors. If accepted tentatively, they mean that, since at 25° rhodopsin has a molar extinction in aqueous solution of 40,600 (ref. 13) and about the same extinction in glycerol–water mixtures, its molar extinction at −195° is about 64,000. Also, since the molar extinction of isorhodopsin at room temperature is 43,000, and rises as does that of rhodopsin on cooling, its molar extinction at − 195° is about 68,000.

Pre-lumirhodopsin. When rhodopsin is irradiated at −195° with blue light (436 or 440 mμ), λ_{max} shifts from 505 to about 517 mμ (Fig. 1, curve 3, 5). The maximum extinction falls slightly, but there is a broad rise of extinction at long wave-lengths, owing to the formation of pre-lumirhodopsin. The final result of this irradiation is a steady-state mixture of rhodopsin and pre-lumirhodopsin.

To evaluate this mixture, the preparation is warmed to room temperature in the dark. The rhodopsin remains intact, whereas the pre-lumirhodopsin bleaches to retinal and opsin, the retinal immediately combining with the hydroxylamine present to form retinaldehyde oxime. The spectrum of the residual rhodopsin was measured at room temperature, and again after re-cooling to −195° (Fig. 1, curve 6). Finally, the preparation was again warmed to room temperature, bleached completely and re-cooled to −195° (curve 7). This last spectrum displays the absorption band of retinaldehyde oxime (λ_{max} 367 mμ). Since retinaldehyde oxime does not absorb appreciably at wave-lengths longer than 450 mμ, above this wave-length curve 7 represents the effects of impurities and scattering. By subtracting this portion of the spectrum from the other curves, one obtains the true absorption spectra of the other components in the visible region.

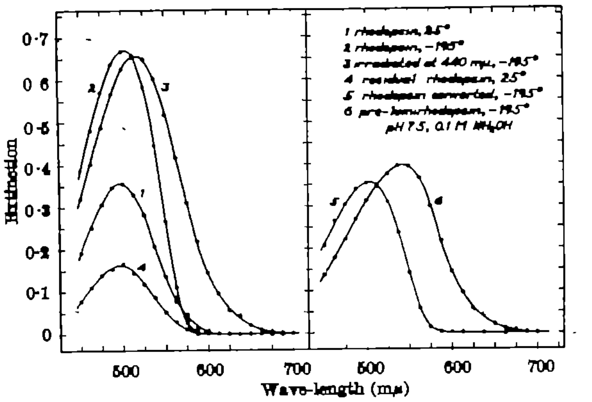

Fig. 2. The spectrum of pre-lumirhodopsin. At the left are shown corrected absorption spectra taken from Fig. 1, except for 4, which is the corrected spectrum of the residual rhodopsin, measured at 25°. The fraction 4/1 represents the proportion of the original rhodopsin remaining in 3; and this fraction of 2 represents its spectrum at −195°. Subtracting this from 3 yields the spectrum of pre-lumirhodopsin (curve 6; λ_{max} 543 mμ). The fraction (1−4)/1 represents the fraction of rhodopsin converted to pre-lumirhodopsin; and this fraction of curve 2 yields its spectrum at −195° (curve 5). Curves 5 and 6 therefore represent the spectra of equivalent concentrations of rhodopsin and pre-lumirhodopsin

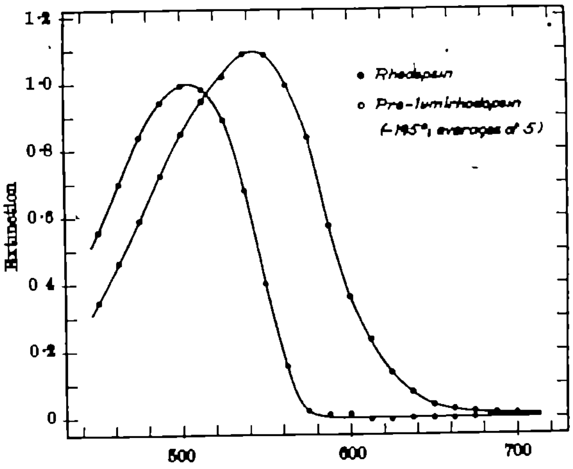

Fig. 3. Absorption spectra of equivalent concentrations of cattle rhodopsin and pre-lumirhodopsin in glycerol–water glasses at liquid nitrogen temperature. Averages from five experiments. Rhodopsin (λ_{max} 505 mμ) is here given arbitrarily the maximal extinction 1·0. Pre-lumirhodopsin (λ_{max} 543 mμ) then has the maximal extinction 1·13

Such corrected absorption spectra, taken from the results in Fig. 1, are shown in Fig. 2. Curve 1 is rhodopsin at room temperature, curve 2 the same preparation at −195°. Curve 3 is the product of irradiation at 440 mμ, a mixture of rhodopsin and pre-lumirhodopsin. Curve 4 is the rhodopsin in this mixture, left after warming the solution to allow the pre-lumirhodopsin to bleach. As already said, this residual rhodopsin was measured both at room temperature and at −195°. The latter spectrum (Fig. 1, curve 6), subtracted from curve 3, yields directly the absorption spectrum of pre-lumirhodopsin. Because, however, a second cooling involves a different pattern of cracking of the solvent, and might introduce an error, we have preferred to use the spectrum of the residual rhodopsin measured in the warm (Fig. 2, curve 4). The ratio of this to curve 1 represents the fraction of the original rhodopsin present in curve 3. This ratio—about 0·45—of curve 2 represents the spectrum of the residual rhodopsin at −195° present in curve 3. Subtracting this from curve 3 yields the spectrum of pre-lumirhodopsin (curve 6). Curve 4 subtracted from curve 1 represents the amount of rhodopsin converted to pre-lumirhodopsin; and this fraction (about 0·55) of curve 2 is shown as curve 5. Curves 5 and 6 therefore show the absorption spectra of equivalent amounts of rhodopsin and pre-lumirhodopsin at −195°.

Repeated experiments of this kind have yielded very similar results. The averages of 5 sets of such measurements are shown in Fig. 3. The average λ_{max} of pre-lumirhodopsin is 543 mμ, and its maximal extinction is on the average 1·13 times that of rhodopsin. We can therefore assign to it tentatively the molar extinction 72,000 at −195°.

Interconvertibility of rhodopsin, pre-lumirhodopsin and isorhodopsin. The conversion of rhodopsin to pre-lumirhodopsin appears to involve only the isomerization by light of the 11-*cis* chromophore to all-*trans*. We used to distinguish between photosensitive and light-stable components of visual systems; but in the sense that they are isomerized by light, all forms of retinal, free and bound, are photosensitive. Their irradiation in all circumstances ends in steady-state mixtures of isomers. The composition of such mixtures depends on the wave-length of the incident light: the steady-state mixture always consists predominantly of those isomers the

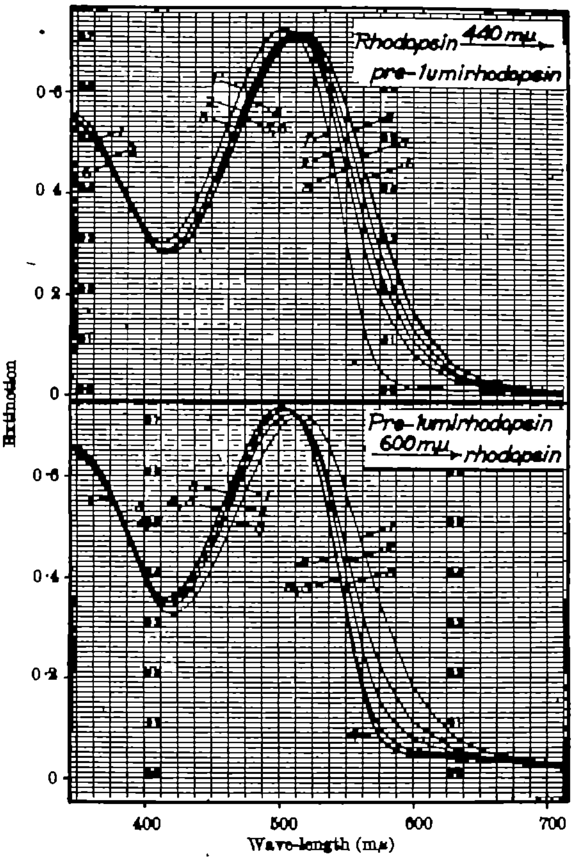

Fig. 4. Course of isomerization of rhodopsin by irradiation at 440 mμ to a steady-state mixture of rhodopsin and pre-lumirhodopsin (above); and the reversion of this mixture to rhodopsin by irradiation at 600 mμ (below). Above, curve 1: cattle rhodopsin in 55 per cent glycerol in water at −195°. Curves 2–6: products of irradiation at 440 mμ for successive periods of 5, 5, 10, 20 and 40 min. Below: the product of irradiating rhodopsin at −195° with 440 mμ (curve 1) is re-irradiated at 600 mμ for successive periods of 5, 5, 10 and 25 min (curves 2–5). Curve 5 almost coincides with *a*, the spectrum of the original rhodopsin, but lies at slightly shorter wave-lengths, owing to the formation of a trace of isorhodopsin. The main processes here are the conversion of a fraction of the rhodopsin (about 55 per cent) to pre-lumirhodopsin (above), and its reversion to rhodopsin (below). The presence of an isosbestic point at about 512·5 mμ in both transformations indicates that only these two components are involved

absorptions of which lie farthest away from the incident radiation. Thus, irradiation with blue light drives the mixture predominantly toward its red-absorbing components, whereas irradiation with red light drives it toward its blue-absorbing components[8]. If one could irradiate at a wave-length that all the isomers but one could absorb, the entire product would be trapped in the form of that transparent isomer. In the present instance, irradiation at 440 mμ drives the steady-state almost entirely toward rhodopsin and pre-lumirhodopsin, and away from the shorter wave-length isorhodopsin (9-*cis* chromophore).

Irradiation at 440 mμ having produced this steady-state mixture (Fig. 1, curve 3), re-irradiation with light of wave-length 600 mμ drives the spectrum almost exactly back to that of rhodopsin (curve 4)—actually just perceptibly to shorter wave-lengths, owing to the formation of a trace of isorhodopsin. More isorhodopsin is not formed because all-*trans* retinal, here the chromophore of pre-lumirhodopsin, isomerizes much more rapidly to the 11-*cis* configuration (that is, to rhodopsin) than to 9-*cis* (isorhodopsin)[8]; and the rhodopsin, once formed, is not isomerized further because at − 195° it scarcely absorbs at 600 mμ.

On re-irradiating at 440 mμ, the spectrum moves back to its earlier position, that of the mixture of rhodopsin and pre-lumirhodopsin (Fig. 1, curve 5). This experiment shows that rhodopsin and pre-lumirhodopsin are almost perfectly interconvertible by light at −195°.

Fig. 4 shows the kinetics of these interconversions: the transformation of rhodopsin by irradiation at 440 mμ into the steady-state mixture of rhodopsin and pre-lumirhodopsin (top); and the reversion of this mixture by irradiation at 600 mμ to rhodopsin (bottom). The presence of a sharp isosbestic point at about 512·5 mμ as the reaction proceeds in either direction is an assurance that it involves only these two components. The formation of a just distinguishable trace of isorhodopsin by irradiation at 600 mμ scarcely disturbs these relationships, for the reason already noted: that rhodopsin scarcely absorbs at this wave-length, and hence is not isomerized by it.

If, however, one irradiates with a wave-length that rhodopsin does absorb—say 546 mμ—the steady-state is shifted very largely toward isorhodopsin. This is shown in Fig. 5. Irradiation of the original rhodopsin at −195° with the mercury green line (546 mμ) shifts the spectrum from curve 2 to 3. Irradiation of this product at 436 mμ shifts it to curve 4—the familiar steady state mixture of rhodopsin and pre-lumirhodopsin. Re-irradiation at 546 mμ brings it back to curve 5, coincident with curve 3. Warming this product to room temperature in the dark reveals a residual light-sensitive pigment with λ_{max} at 489 mμ (curve 6), close to that of cattle isorhodopsin (485 mμ). The final product of irradiation at 546 mμ is therefore mainly isorhodopsin, with less rhodopsin and still less pre-lumirhodopsin, the latter principally accounting for the rise of extinction at long wave-lengths (curves 3 and 5, compared with 2).

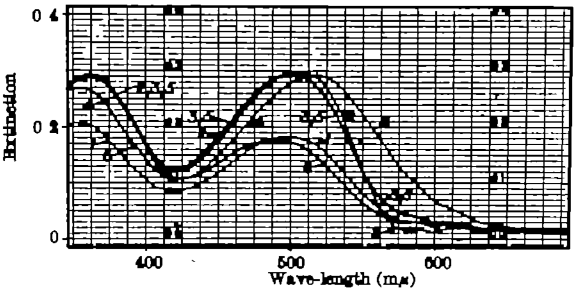

Fig. 5. Interconversions of rhodopsin, pre-lumirhodopsin and isorhodopsin at −195°. 1, Cattle rhodopsin in a glycerol–water mixture (2 : 1) at 24·5°. On cooling to −195° the spectrum went to 2. On long irradiation at 546 mμ it was displaced to 3, representing a steady-state mixture of isorhodopsin with lesser amounts of rhodopsin and pre-lumirhodopsin. On re-irradiation at 436 mμ it went to 4, representing a steady-state mixture of rhodopsin and pre-lumirhodopsin (about 45 : 55). On re-irradiation at 546 mμ the spectrum returned to 5, which coincides with 3. On warming to 24·5° it went to 6; the pre-lumirhodopsin in 5 had bleached to all-*trans* retinal and opsin, leaving a residue of isorhodopsin (λ_{max} 485 mμ) mixed with a lesser amount of rhodopsin

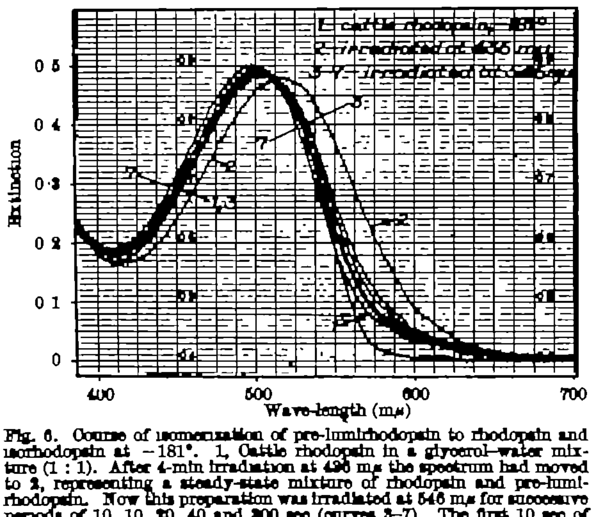

Fig. 6. Course of isomerization of pre-lumirhodopsin to rhodopsin and isorhodopsin at −181°. 1, Cattle rhodopsin in a glycerol–water mixture (1 : 1). After 4-min irradiation at 436 mμ the spectrum had moved to 2, representing a steady-state mixture of rhodopsin and pre-lumirhodopsin. Now this preparation was irradiated at 546 mμ for successive periods of 10, 10, 20, 40 and 300 sec (curves 3–7). The first 10 sec of irradiation brought the spectrum almost back to that of rhodopsin; further irradiation only slowly displaced the spectrum toward shorter wave-lengths. This behaviour is an expression of the fact that the all-*trans* chromophore of pre-lumirhodopsin isomerizes much more readily to 11-*cis* (rhodopsin) than to 9-*cis* (isorhodopsin), the principal component in the final steady-state

The steady-state product at 436 mμ is transformed into the steady-state product at 546 mμ by a peculiar route. This is shown in Fig. 6. The experiment begins with the irradiation of rhodopsin (curve 1) at 436 mμ to produce the usual steady-state mixture of rhodopsin and pre-lumirhodopsin (curve 2). This, then, is irradiated at 546 mμ, eventually to arrive at curve 7, representing mainly isorhodopsin, with small admixtures of rhodopsin and pre-lumirhodopsin. The significant point is that the first 10 sec of irradiation at 546 mμ has so much greater effect than the next 10 sec and all subsequent irradiations. The first such irradiation brings λ_{max} from about 517 to 506 mμ (curve 3), close to that of rhodopsin; whereas another 370 sec of irradiation are needed to bring λ_{max} to about 497 mμ (curve 7), close to that of isorhodopsin. It was shown some time ago that, at −20°, metarhodopsin isomerizes with a much higher quantum efficiency to rhodopsin than to isorhodopsin[8]. Apparently the same is true of pre-lumirhodopsin at liquid nitrogen temperature. The first 10 sec of irradiation convert pre-lumirhodopsin largely to rhodopsin, whereas further irradiation at this wave-length only slowly drives the steady-state over toward isorhodopsin. These mechanisms are discussed further later on.

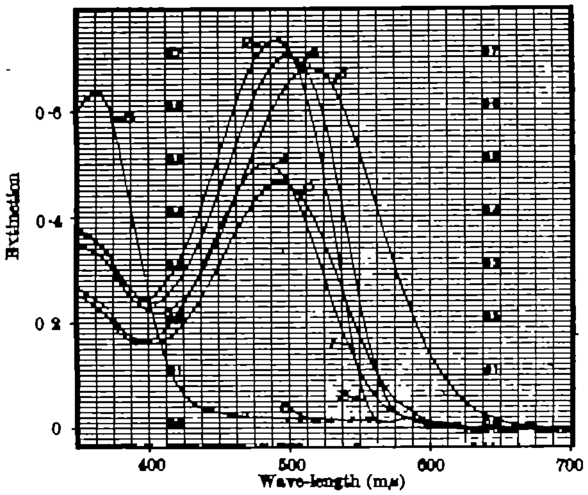

Fig. 7. Interconversions of cattle isorhodopsin, pre-lumirhodopsin and rhodopsin at −195°. 1, Isorhodopsin synthesized by incubating cattle opsin with 9-*cis* retinal, in glycerol–water (2 : 1) containing 0·1 M hydroxylamine, at *p*H 7·5, 22·5°. 2, The same at −195°. Irradiation at 436 mμ for 256 sec brings the spectrum to 3, the same steady-state mixture of rhodopsin and pre-lumirhodopsin (about 45 : 55) that is obtained by a similar irradiation of rhodopsin. Re-irradiation at 579 mμ for 32 sec brings the spectrum to 4; this is now a mixture of rhodopsin with a minor amount of isorhodopsin, as shown by warming in the dark to 20° (curve 5). Finally the preparation was bleached completely at 20° to yield curve 6, displaying the absorption band of retinene oxime at 367 mμ

Alternatively, one can begin such an experiment with isorhodopsin (Fig. 7). This was prepared by incubating cattle opsin with 9-*cis* retinal. On cooling to −195°, its spectrum rose from curve 1 to 2, λ_{max} being displaced from about 485 mμ at room temperature to 491 mμ in the cold. Irradiation at 436 mμ yields the same steady-state mixture of rhodopsin and pre-lumirhodopsin as one obtains by irradiating rhodopsin (curve 3). Re-irradiating this mixture at 579 mμ drives the spectrum back to curve 4 (λ_{max} 500 mμ); and warming the preparation in the dark to room temperature shows this to be rhodopsin, with a small admixture of isorhodopsin (λ_{max} 494 mμ). Other experiments have shown that if this last irradiation had been performed at 600 mμ, we would have obtained almost pure rhodopsin.

These experiments demonstrate the well-nigh perfect interconvertibility of rhodopsin, isorhodopsin and pre-lumirhodopsin by light at −195°. Apparently at this temperature light activates only the geometric isomerization of the chromophores, leaving the protein relatively unaltered.

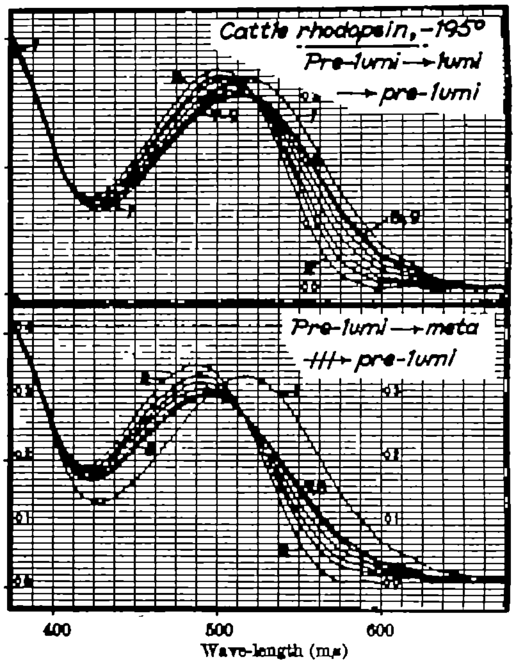

Fig. 8. Demonstration that irradiation at −195° can convert lumirhodopsin to pre-lumirhodopsin (above), but not metarhodopsin to pre-lumirhodopsin (below). Above, cattle rhodopsin in glycerol–water (2 : 1) containing M/10 hydroxylamine, at *p*H 7·5, was irradiated at 436 mμ to a steady-state mixture of rhodopsin and pre-lumirhodopsin curve 1). On warming to −90° in the dark, the pre-lumirhodopsin was converted to lumirhodopsin; and on re-cooling to −195° this—still mixed with rhodopsin—yielded curve 2. Now re-irradiation at 436 mμ brought the spectrum from 2 to 9, which possesses the same λ_{max} though a slightly lower extinction than 1, showing that this irradiation had re-converted lumi- to pre-lumirhodopsin. Below, irradiation of a similar preparation at 436 mμ and −195° produced a similar mixture of rhodopsin and pre-lumirhodopsin (curve 1). This was warmed to −15° to permit the pre-lumirhodopsin to be converted to metarhodopsin. On re-cooling to −195° the mixture of rhodopsin and metarhodopsin yielded curve 2. Long irradiation at 436 mμ brought the spectrum from 2 to 8: the rhodopsin in 2 had formed the usual steady-state mixture of rhodopsin and pre-lumirhodopsin, but the metarhodopsin was unchanged

Interconvertibility of pre-lumi- and lumi-rhodopsin. Hubbard, Brown and Kropf have shown that rhodopsin and lumirhodopsin are interconvertible by light at −65° (ref. 14). The experiments of Yoshizawa and Kitô implied that the irradiation of lumirhodopsin at liquid nitrogen temperature also causes a partial reversion to rhodopsin, and hence potentially to pre-lumirhodopsin[15].

Fig. 8 (top) shows the reversion of lumi- to pre-lumi-rhodopsin at −195°. Cattle rhodopsin was repeatedly brought back and forth between −195° and −90° until it had settled down to a fairly constant E_{max} at −195° (0·350). On irradiating at 436 mμ, its spectrum moved to curve 1, representing the usual steady-state mixture of rhodopsin and pre-lumirhodopsin. On warming this in the dark to −90°, then re-cooling to −195°, the spectrum had changed to curve 2: the pre-lumirhodopsin had changed to lumirhodopsin, still accompanied by rhodopsin. On re-irradiating at 436 mμ (−195°), the spectrum gradually shifted from (2) to (9), that is, back to the steady-state mixture of rhodopsin and pre-lumirhodopsin. The slight fall of E_{max} may represent a trivial discrepancy associated with the warming and re-cooling, or possibly some modification of pigment by the long irradiation. The sharp isosbestic point at about 523 mμ indicates the transformation of a single precursor into a product, in this case lumirhodopsin into pre-lumirhodopsin.

A specially designed experiment shows that this transformation requires light. Rhodopsin was cooled to −136° and irradiated with 436 mμ to the steady-state mixture of rhodopsin and pre-lumirhodopsin. Warming to −90° converted the latter to lumirhodopsin. This did not change on being re-cooled to −134° and held at that temperature for 1·5 h in the dark.

Failure of metarhodopsin to revert to pre-lumirhodopsin at −195°. At −20°, rhodopsin and metarhodopsin are freely interconvertible by irradiation[9]. At −65°, however, irradiating rhodopsin yields lumi- but not meta-rhodopsin; and conversely irradiating metarhodopsin yields no lumirhodopsin or rhodopsin. The change from lumi- to meta-rhodopsin appears to involve a rearrangement in the structure of opsin, apparently blocked in both directions at this low temperature[14].

The lower portion of Fig. 8 shows an experiment to test the possibility that metarhodopsin can revert to rhodopsin and pre-lumirhodopsin at −195°. Like the preceding experiment, this was begun by bringing the rhodopsin preparation back and forth repeatedly between −195° and −20° until a reasonably stable E_{max} was achieved at −195° (0·34). Then it was irradiated at 436 mμ to yield the usual steady-state mixture of about 45 per cent rhodopsin and 55 per cent pre-lumirhodopsin (curve 1). The preparation was now warmed to −15° in the dark to permit all the pre-lumirhodopsin to be converted to metarhodopsin, and was re-cooled to −195° (curve 2). The resultant mixture of metarhodopsin and rhodopsin (about 55 : 45) has λ_{max} 487 mμ. On re-irradiating at 436 mμ at this temperature, the spectrum changed gradually from (2) to (3). The source of this change is the conversion of the rhodopsin present in (2) to the usual steady-state mixture of rhodopsin and pre-lumirhodopsin. The composition of the final mixture, if no change has occurred in the metarhodopsin, is expected to be about 55 per cent metarhodopsin, 20 per cent rhodopsin (that is, 0·45 × 0·45), and 25 per cent pre-lumirhodopsin (that is, 0·55 × 0·45). The shape and position of curve 3 (λ_{max} 496 mμ) agree reasonably well with this prediction. It is concluded that metarhodopsin does not revert to rhodopsin (or pre-lumirhodopsin) at −195°.

Temperature-stability ranges. In Fig. 9 a preparation of rhodopsin, having been irradiated at −195° with light of wave-length 436 mμ to produce the steady-state mixture of rhodopsin and pre-lumirhodopsin with λ_{max} 517 mμ, was allowed to warm slowly in the absorption vessel in the dark. Periodically it was re-cooled to −195° and its spectrum re-measured. The figure shows the change of λ_{max} at −195°.

As the temperature rises, the pre-lumirhodopsin in the original steady-state mixture remains stable to about —140°. Then λ_{max} shifts to about 500 mμ, as pre-lumirhidopsin goes over to lumirhodopsin. This remains stable to about −40°; then λ_{max} shifts again, to about 487 mμ, as lumi- goes over to meta-rhodopsin. Above 0°, λ_{max} in the visible region rises to about 499 mμ, as metarhodopsin is hydrolysed to retinal and opsin, leaving a residue of rhodopsin mixed with a little isorhodopsin. Simultaneously a new absorption band appears in the ultra-violet (367 mμ), owing to the formation of retinaldehyde oxime. If this experiment is begun with isorhodopsin rather than rhodopsin, the results are the same.

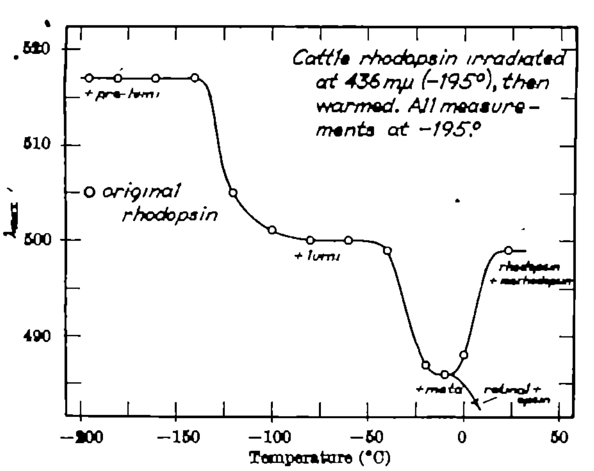

Fig. 9. Stepwise bleaching of rhodopsin by gradual warming. Cattle rhodopsin at −195° (λ_{max} 505 mμ) was irradiated at 436 mμ to the steady-state mixture of rhodopsin and pre-lumirhodopsin (λ_{max} 517 mμ). Then the preparation was allowed to warm to various temperatures, and each time was re-cooled to −195° and its spectrum re-measured. Its λ_{max} remained unchanged to about −140°. Then it fell to about 500 mμ, as pre-lumirhodopsin went over to lumirhodopsin. Above about −40° it fell again, to about 487 mμ, as lumirhodopsin formed metarhodopsin. Above 0° it rose again in the visible region, as metarhodopsin bleached to all-*trans* retinal and opsin (λ_{max} 387 mμ, not shown), leaving a residue of rhodopsin mixed with a small amount of isorhodopsin (λ_{max} 499 mμ)

Discussion

Throughout these experiments we have to deal with two kinds of change: the geometrical isomerization of retinaldehyde chromophores activated by light, and associated rearrangements of the protein, opsin. These two types of process stand in the relation of independent and dependent variable, and lead on the irradiation of rhodopsin or isorhodopsin to a succession of products, the interrelationships of which are shown in Fig. 10.

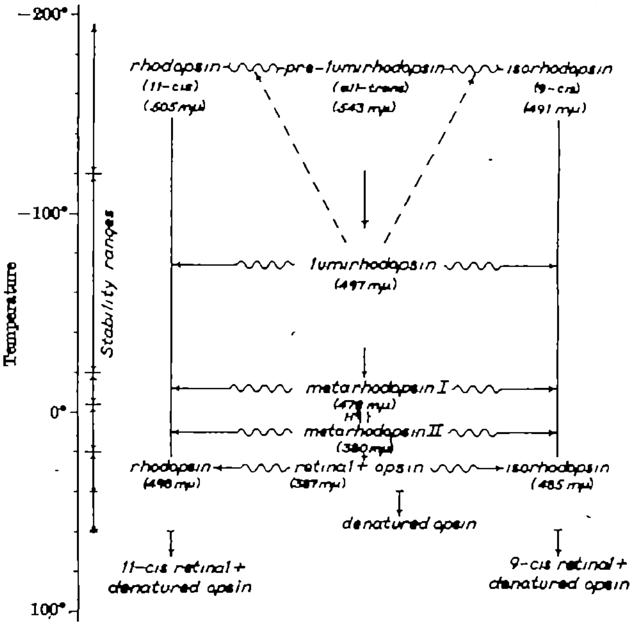

Fig. 10. Diagram showing inter-relationships of photochemical and thermal reactions of rhodopsin and isorhodopsin, arranged on a temperature scale. Photoreactions are symbolized by wavy lines, thermal reactions by straight lines, and sequences of both by both symbols in succession. The stability ranges of the various molecular species are bracketed by transitional temperatures at which the reactions are half completed in about 10 min (that is, fully completed in about 1 h). This diagram is extended to include also data on heat denaturation; heat bleaches rhodopsin and isorhodopsin by changing the configuration of opsin, whereas light does so by isomerizing retinal (ref. 16). Metarhodopsins I and II represent tautomeric forms of metarhodopsin in equilibrium with each other, higher temperatures, acidity or a higher proportion of glycerol in the medium favouring metarhodopsin II (ref. 17)

The geometrical isomerization of the chromophores is a typical photochemical reaction which can be completed in a rigid solvent at −195° C. It is responsible for instituting at that temperature perfectly reversible steady-states among rhodopsin, pre-lumirhodopsin and isorhodopsin, the final composition of which depends on the wave-length of irradiation, tending always to absorb the incident radiation minimally.

Certain circumstances govern the pathways by which these steady-states are achieved in the cold. Each geometric isomer of retinal, whether free or the chromophore of a visual pigment, is raised by the absorption of a photon to its own excited state, different from that of other geometric isomers; and each double bond isomerizes independently of the others[18]. (If the geometric isomers of retinal possessed a common excited state, *cis* isomers should require less energy to reach this than the all-*trans* isomer, since the ground states of *cis* isomers lie at higher energy-levels than that of all-*trans* retinal. Hence the absorption spectra of *cis* isomers should lie at *longer* wave-lengths than that of all-*trans* retinal; whereas in fact they lie at *shorter* wave-lengths. One can conclude not only that there is no common excited state but also that the energy-levels of *cis* isomers must lie even farther above all-*trans* in the excited than in the ground states.) Thus 11-*cis* retinal, for example, on absorbing a photon, may isomerize to all-*trans*; and this, on absorbing another photon, may isomerize to another *cis* configuration. For this reason interconversions between rhodopsin and isorhodopsin must involve multiple light absorptions, and must go through pre-lumirhodopsin at −195°, just as they must go through lumirhodopsin, or metarhodopsin, or all-*trans* retinal and opsin at higher temperatures.

A second condition involves the quantum efficiencies of these isomerizations. Hubbard and Kropf[8] have shown that the quantum efficiencies for interconversions among rhodopsin, metarhodopsin and isorhodopsin at −20° stand in the ratio.

$$\text{rhodopsin} \underset{0\cdot5}{\overset{1}{\rightleftharpoons}} \text{metarhodopsin} \underset{0\cdot3}{\overset{0\cdot1}{\rightleftharpoons}} \text{isorhodopsin}$$

Since photoisomerizations play the primary part in these reactions, probably about the same relationships obtain at −195°, when pre-lumirhodopsin takes the place of metarhodopsin.

This array of quantum efficiencies explains why the irradiation of a mixture of rhodopsin and pre-lumirhodopsin (about 45 : 55) at 600 mμ produces only a trace of isorhodopsin (cf. Fig. 1, 4). At −195°, neither rhodopsin nor isorhodopsin absorbs the 600 mμ radiation, which acts therefore only on pre-lumirhodopsin, converting it to rhodopsin and isorhodopsin in the proportion 5 : 1, set by the ratio of quantum efficiencies. The steady-state is therefore expected to contain the original rhodopsin (45 parts), rhodopsin newly formed from 5/6 of the pre-lumirhodopsin (55 × 5/6 = 46 parts), and the remainder —9 per cent—isorhodopsin. This estimate is reasonably consistent with the small displacement of spectrum that is observed (cf. Fig. 1, curve 4, compared with 2). (It should be conceded that owing to the slow formation of isorhodopsin under the conditions of these experiments, we may not have wholly reached the steady-state by curve 4 in Fig. 1 or curve 5 in Fig. 4 (bottom).)

These relative quantum efficiencies also explain the peculiar approach to the steady-state shown in Fig. 6, in which irradiation at 546 mμ very rapidly institutes a transitory steady-state between pre-lumirhodopsin and rhodopsin, but only slowly brings these into a final steady-state with isorhodopsin. These transformations involve a considerable conversion of rhodopsin to isorhodopsin, which for reasons already stated must go through pre-lumirhodopsin.

On gradually warming pre-lumirhodopsin in the dark, it undergoes the stepwise series of thermal rearrangements shown on a temperature scale in Fig. 10. An accumulation of aberrations in our own and other workers' observations over the years have led us lately to re-examine metarhodopsin. We find it to involve two tautomeric forms in equilibrium with each other, metarhodopsin I (λ_{max} about 478 mμ in cattle preparations), which forms first, entering into an equilibrium with metarhodopsin II (380 mμ), in which raising the temperature, acidity or the proportion of glycerol in the medium favours metarhodopsin II (ref. 17). It will be noted that all our references to metarhodopsin here involve metarhodopsin I. Finally, all-*trans* retinal hydrolyses from opsin, to which it had apparently been bound in all these chromophores as a Schiff base:

$$C_{19}H_{27}CH{=}N\text{—opsin} + H_2O \rightarrow$$
$$C_{19}H_{27}CHO\ (\text{retinal}) + \text{opsin—}NH_2$$

These changes—except perhaps the last—involve progressive rearrangements in the structure of opsin. One consequence is to expose new reactive groups, not available to reagents in rhodopsin itself. When bleaching is completed, two sulphydryl groups and one proton-binding group with pK about 6·6 (imidazole ?) have been exposed; and preliminary experiments show that the latter group is available by the time metarhodopsin II has formed[19]. It seems probable that this opening up of opsin structure is a decisive event in visual excitation[20].

The isomerization of retinal to the 11-*cis* or 9-*cis* configuration makes possible the regeneration of rhodopsin or isorhodopsin. In forming these pigments, opsin adjusts its structure to these configurations of retinal. Perhaps better said, opsin and the chromophores assume geometries that fit together, and are stabilized in the combination by mutual interactions. No other configuration of retinal can produce this effect; so that the isomerization of the 11-*cis* or 9-*cis* chromophore to all-*trans* promptly makes the combination unstable.

For opsin to adapt its structure to 11-*cis* or 9-*cis* retinal, temperatures are needed at which the requisite re-arrangements can occur. At room temperature, all of them can occur, and opsin combines spontaneously with either isomer. Opsin as it exists in metarhodopsin can still re-arrange at −20° to form rhodopsin or isorhodopsin, but can no longer do so below −50° (ref. 14; Fig. 8, bottom). Opsin as it exists in lumirhodopsin can re-arrange to form rhodopsin or isorhodopsin even at −195° (upper part of Fig. 8). To the degree that the configuration of opsin is moulded specifically by its combination with 11-*cis* or 9-*cis* retinal, lumirhodopsin can be transformed to pre-lumirhodopsin only over rhodopsin or isorhodopsin. Light probably must first isomerize the all-*trans* chromophore of lumirhodopsin to 11-*cis* or 9-*cis*, so inducing the rearrangements of opsin needed to form rhodopsin or isorhodopsin. Then, by the absorption of another photon at −195°, the chromophores of these pigments are isomerized back to all-*trans*, forming pre-lumirhodopsin.

It is possible that light has another kind of effect in such reactions. None of the reactions being discussed is highly endergonic, so that whether or not the absorption of a photon causes isomerization of the chromophore, a large residue of the absorbed energy should remain available. This might be important, particularly at low temperatures, in activating protein rearrangements, either through a localized excitation of protein groups, or, the residual energy having been degraded into heat, through a more general 'melting' effect on the protein in the neighbourhood of the chromophore. Light could scarcely have such effects, however, without simultaneously isomerizing retinal; so that one should assume the photo-isomerization mechanism in any event, perhaps aided secondarily by excitation or 'melting' of the protein.

A final problem involves the spectrum of pre-lumirhodopsin. Kropf and Hubbard[8,21] have attempted to account for the spectrum of rhodopsin as follows: the combination with opsin in a Schiff base linkage ($C_{19}H_{27}CH{=}N$—opsin) should shift the λ_{max} of 11-*cis* retinal (380 mμ) to about 367 mμ. Protonation of the Schiff base (that is, $C_{19}H_{27}CH{=}NH^{+}$—opsin) is expected to raise λ_{max} to about 440 mμ (ref. 22). It was suggested that the farther shift of spectrum to the λ_{max} of rhodopsin (498 mμ) is associated with the lowering of the energy-level of the excited state, owing to interactions between the conjugated side-chain of 11-*cis* retinal and opsin, for which closeness of fit is prerequisite. That is, 11-*cis* retinal, and to a lesser extent the 9-*cis* isomer, are good chromophores because they *fit* opsin—after the necessary rearrangements—better than do other isomers. By the same token, any loosening of fit between opsin and its chromophore should weaken their mutual interactions and shift the spectrum toward the blue.

How then do we account for the λ_{max} of pre-lumirhodopsin ? Since it lies far toward the red from rhodopsin, does that imply that its all-*trans* chromophore fits opsin

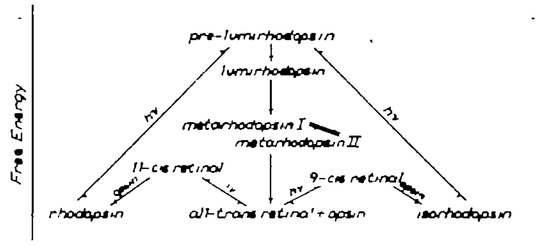

Fig. 11. Diagram showing the order in which intermediates in the bleaching and regeneration of rhodopsin and isorhodopsin lie on a scale of relative free energies (chemical potentials). Relative distances on the energy scale mean little in this diagram; only the order is important

even more closely, and interacts with it more strongly, than the 11-*cis* chromophore? But why then is pre-lumirhodopsin unstable?

The same problem has arisen earlier with regard to lumirhodopsin. The spectra of some vertebrate lumirhodopsins lie at longer wave-lengths than the corresponding rhodopsins (bull-frog, 7 mμ; cusk, 19 mμ longer[14]). Such displacements of spectrum might at least in part be explained simply, for the change of configuration from 11-*cis* to all-*trans* in itself involves a shift of $\lambda_{\max}$ toward the red, about 7 mμ in free retinal, and perhaps much more in the chromophores of visual pigments. This red shift might perhaps more than counterbalance the opposed tendency toward a blue shift owing to loosening of fit. But in the squid, lumirhodopsin lies about 50 mμ toward the red from rhodopsin[14]; and here as in cattle pre-lumirhodopsin such an explanation seems inadequate.

A consideration of the order of rhodopsin, isorhodopsin and the intermediates of their bleaching on a free energy (chemical potential) scale offers the way out of this dilemma (Fig. 11). The arrangement here is dictated by the direction of spontaneous change in the case of the thermal reactions. The existence of thermal equilibria also permits us to assign a ΔF_s of about 2 kcal for the isomerization of all-*trans* retinal to 11-*cis* (ref. 23); and about −0·5 kcal for the change from metarhodopsin I to II in neutral 33 per cent glycerol at 20° (ref. 17). No other numerical values are yet available, and the figure shows otherwise only qualitative relationships.

What emerges is that the ground-state of pre-lumirhodopsin lies at a considerably higher energy than those of rhodopsin or isorhodopsin—sufficiently higher to encompass all the intervening states. This large rise in the energy-level of the ground state of pre-lumirhodopsin, if not accompanied by a comparable rise in the level of the first electronically excited state, would mean shorter transitions to the excited state, so explaining the shift of absorption spectrum toward the red. Indeed, the shift of spectrum offers a suggestion of how high the ground state of pre-lumirhodopsin may lie above those of its precursors, if one assumes tentatively that all these molecules differ relatively little in the levels of their first excited states. At −195° the shift of the $\lambda_{\max}$ of pre-lumirhodopsin toward the red implies on this basis that its free energy-level in the ground state may lie 3·9 kcal higher than that of rhodopsin, and about 5·5 kcal higher than that of isorhodopsin. (These estimates are based on the formula, $\Delta E = 28{,}540 \left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2} \right)$, in which λ_1 and λ_2 are the shorter and longer wave-length maxima in mμ, and ΔE is the difference in energy of the absorbed quanta in kcal per mole. They involve sufficient uncertainty so that we have not tried to express implied differences in the free energies of rhodopsin and isorhodopsin in Fig. 11.)

We would suggest therefore that this rise in the energy-level of the ground state of pre-lumirhodopsin, by shortening the transition to its first electronically excited state, accounts for its long $\lambda_{\max}$. The effects of light on rhodopsin and isorhodopsin are probably best envisaged as follows: These pigments, as suggested by Hubbard and Kropf, owe their long wave-length spectra in part to the lowering of their first excited states by interactions between their chromophores and opsin dependent on closeness of fit. When the absorption of a photon isomerizes the chromophore of rhodopsin or isorhodopsin to all-*trans*, the side-chain interactions already established with opsin continue to hold both chromophore and opsin in what is now a highly constrained and distorted geometry. This is then pre-lumirhodopsin. The essential point is not that in pre-lumirhodopsin the all-*trans* chromophore fits opsin better—it probably fits less well; but that the strained condition of this molecule represents a large rise in the energy of its ground state, making it on one hand highly unstable, and also shortening the transition to the first electronically excited state, so displacing its spectrum toward the red.

Lumirhodopsin and metarhodopsin I then represent stages in the progressive relaxation of these constraints, opsin approaching more and more closely the configuration of the free protein, and retinal its normal all-*trans* geometry. As the fit between these components grows increasingly poorer, the interactions between them are correspondingly weaker and the energy-level of the ground state falls. Transitions to the first excited state therefore grow longer, and the spectrum shifts increasingly toward the blue. By metarhodopsin II, mutual interactions between retinal and opsin are at a minimum and the chromophore has lost its proton; the spectrum, as should be true of a Schiff base, lies at shorter wave-lengths than that of free all-*trans* retinal. All that remains is to hydrolyse retinal from opsin.

One of us (T. Y.), on leave of absence from Osaka University, occupies a research fellowship at Harvard University with funds provided by the National Science Foundation. This investigation was further supported with funds granted to the other (G. W.) by the National Science Foundation and the Office of Naval Research. We thank Mr. Paul K. Brown of this laboratory for help with designing and building the absorption vessel.

LETTERS TO THE EDITOR

PHYSICS

Special Theory of Relativity

Prof. H. Dingle has sent me a reprint of his communication published under the above title on p. 985 of *Nature*, September 8, 1962, with the handwritten remark: "With kindest regards. Test case for the integrity of scientists".

Though former experience has taught me that discussing relativity with Dingle leads to no agreement I have to answer a challenge which is directed against the "scientific integrity" of myself and of others.

I use Dingle's notation. He restricts himself to the case of a linear motion along the x- or ξ-axis.

$K(x,t)$ is a 'stationary' system of reference, $k(\xi,\tau)$ a 'moving' one. Dingle writes down half the Lorentz transformation expressing τ by t and x, and half its inverse expressing t by τ and ξ. Then he quotes a passage from Einstein's paper, the first paragraph of which ends with the question: "*What is the rate of this clock, when viewed from the stationary system?*". Then follows the well-known derivation of the formula

$$\tau = t\sqrt{(1 - v^2/c^2)} \qquad (1)$$

Dingle now proceeds in this way: "And here is the passage leading to the opposite conclusion". The first paragraph of this new passage is completely identical with that of the original including the last sentence just quoted (in italics). Then he exchanges the co-ordinate systems and so obtains the result:

$$t = \tau\sqrt{(1 - v^2/c^2)} \qquad (2)$$

which he regards as a contradiction to formula (1).

The mistake is in the first paragraph quoted above (in italics); it should read, in the two cases:

1st case, clock at rest in k: *What is the rate of the clock in k, when viewed from the 'stationary' system K ?*

2nd case, clock at rest in K: *What is the rate of the clock in K, when viewed from the 'moving' system k ?*

In other words: formulæ (1) and (2) refer to different physical situations; t and τ have not the same meaning in (1) and (2).

If the clock is at rest in k and in motion relative to K, the reading of the hands of the clock at the beginning of the time-interval t in k is taken at the same place in k as the reading at the end of the time-interval. But the reading of the hands of this clock taken in K at the beginning and at the end of the time-interval are at different positions of the clock in K, as the clock is moving relative to K.

If, on the other hand, the clock is at rest in K and in motion relative to k, the situation is exactly reversed: the beginning and the end position of the clock are read at the same place in K, but at different places in k.

The two cases are therefore different, the symbols t and τ in expressions (1) and (2) referring to different physical situations; these are inverse and must of course correspond to an exchange of the symbols t and τ. This is exactly what expressions (1) and (2) express. There is no contradiction.

Dingle's objections are just a matter of superficial formulation and confusion. The simple fact that all relations between space co-ordinates and time expressed by the Lorentz transformation can be represented geometrically by Minkowski diagrams should suffice to show that there can be no logical contradiction in the theory. The use of such diagrams is explained, for example, in my book *Einstein's Theory of Relativity* of which a new cheap edition (Dover Publications, Inc., New York) is now available. I give here the diagram for the time dilation with a detailed legend (Fig. 1); it shows why the slowing down of a clock at rest in one system when observed from another system in relative motion is reciprocal in the two systems. Further explanations seem to be superfluous.

Max Born

Bad Pyrmont,
West Germany.

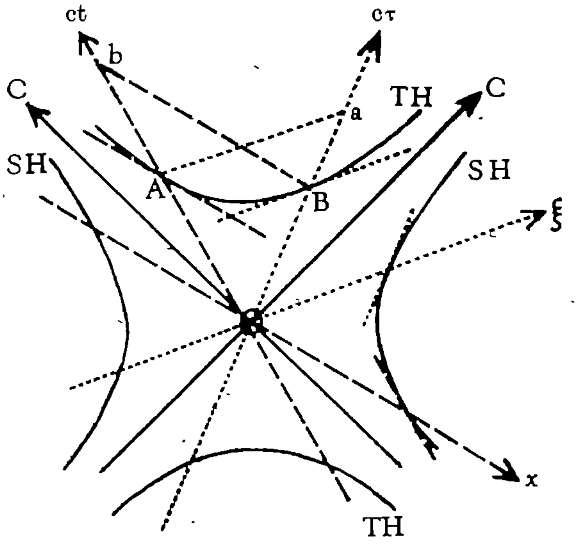

Fig. 1. C,C, Cross-section of light cone; SH, space calibration hyperbola; TH, time calibration hyperpola; x,ct, conjugate diameters = axes in K; $(\xi,\sigma\tau)$, conjugate diameters = axes in k; OA, represents the same time-interval in K as OB in k:

$$OA \sim OB$$

$$\begin{array}{ll} \text{Clock at rest in } K \left\{ \begin{array}{l} OA \sim ct \\ Oa \sim \sigma\tau \end{array} \right\} & \begin{array}{c} Oa > OB \sim OA \\ \tau > t \end{array} \\ \text{Clock at rest in } k \left\{ \begin{array}{l} OB \sim \sigma\tau \\ Ob \sim ct \end{array} \right\} & \begin{array}{c} Ob > OA \sim OB \\ t > \tau \end{array} \end{array}$$

I am grateful to Prof. Born for replying to my communication, and am especially pleased that one scientist of outstanding eminence has passed the integrity test: would there were others.

I must maintain, however, that he has not met the point I raised: this is shown by the following passage in his letter: "The mistake is in the first paragraph . . . the same meaning in (1) and (2)". In making this statement Prof. Born is clearly exceeding his rights: a question cannot be dismissed as a "mistake". It is my question, and I meant it exactly as I put it. Prof. Born substitutes a different question, which he assumes I should have asked, and gives an answer that does not contradict Einstein's conclusion. I agree, but the answer to my question does.

Prof. Born is wrong in saying that my expressions (1) and (2) refer to different physical situations and that t and τ have not the same meaning in (1) and (2). This is not a matter of opinion. I constructed the second statement, and I say categorically that if, in Einstein's statement, A is a clock fixed at the origin of what he calls the 'stationary' system, and X is a clock fixed at the origin of what he calls the 'moving' system, then in my statement also, A is fixed at the origin of that same 'stationary' system and X at the origin of that same 'moving' system. Furthermore, in both statements t is the time of an event according to clock A, and τ the time of the same event according to clock X.

What Einstein's statement shows is that, on his theory, between the two events, (1) the coincidence of the clocks, and (2) a later event occurring on X, the time-interval according to A is greater than that according to X, so that X is running slower than A. What my statement shows is that, in the identical physical situation, between the two events (1) the coincidence of the clocks, and (2) a later event occurring on A, the time-interval according to A is smaller than that according to X, so that X is running faster than A. The only difference between the two cases is that the intervals compared are those between different pairs of events; and the only conceivable way of avoiding the contradiction is by showing (consistently with the relativity postulate, that is, without assuming an ether in which A is uniquely stationary and X uniquely moving) that Einstein's interval between two events on X is valid for comparing the rates of the clocks, and that my interval between two events on A is not.

I repeat that there is only one physical situation—two clocks, A and X, in uniform relative motion; that there is no change of co-ordinate system in going from Einstein's statement to mine (A 'rests' and X 'moves' in both); and that there is no change of meaning of t or τ (t refers in both to readings of A, and τ to readings of X). Hence equations (1) and (2) show that A goes steadily both faster and slower than X.

The effective criterion of truth in these matters still resides in the pronouncements of mathematical physicists, none of whom, of stature comparable with that of Prof. Born, appears to share his sense of obligation on this point; and as I have been informed, with various degrees of emphasis, that my utterances on such things are imponderable, there is an urgent need for the weight of his unquestioned authority to reinforce a clear demonstration of the truth of the matter, whatever it may be.

Fading of Latent Image in Japanese Fuji *ET-7A* and *ET-6B* Nuclear Emulsions

THE various parameters on fading[1-6] indicated experimentally are due to: the action of some constituents of the atmosphere, surrounding temperature, time of storage, and emulsion composition. Based on the available experimental evidence, the mechanism of fading is thought to be dependent on the oxidation of the development specks by atmospheric oxygen in the presence of water[6].

In order to examine the latent image fading effects, the plates were exposed to mono-energetic α-rays, which were prepared from thorium nitrate by 'electrolytic displacement' method[7]. The separated ThC by emitting β-rays transforms to ThC′, which is a pure mono-energetic α-emitter with energy 8·78 MeV; only a few of them originate from ThC (ref. 8).

The plates were irradiated by α-particles from ThC′ and stored in the vessels, under different conditions, for the purpose of examining the various parameters on fading. After insertion of the irradiated plates, the vessels were evacuated to a pressure less than 0·1 mm mercury and the vapour pressure in the vessel was adjusted to what was desired by opening the cork to concentrated sulphuric acid or distilled water, which was stored in the system, then filled with the gas. The vessels containing the exposed plates under the conditions described were stored in a constant-temperature bath which was maintained at 30° C for the assigned duration of times as indicated in Tables 1 and 2 and Figs. 1 and 2. They and the plates just

D/D_0 for *ET-7A*	0·989 ± 0·041	0·961 ± 0·030	0·905 ± 0·038	0·876 ± 0·036
D/D_0 for *ET-6B*	0·941 ± 0·32	0·861 ± 0·031	0·721 ± 0·035	0·672 ± 0·053

irradiated were developed simultaneously with one part *ID*–19 stock solution to 10 parts distilled water at 20° C; special precautions were taken in plate processing aiming at easier grain counting of the developed α-tracks.

To examine the relation between fading rate and storage time, the plates were irradiated at a certain interval several times and processed at the end of the last exposure. Thus the emulsion plates were stored under constant conditions for different periods of time. The fading rate D/D_0 (ratio of the grain density after storage for a time t before development and density after immediate development) and the storage time t in days are given in Table 1 and plotted in Fig. 1. The atmospheres surrounding the plates were nitrogen, oxygen or argon and the vapour pressure of the atmospheres was 19·09 mm mercury corresponding to the relative humidity of 60 per cent at 30° C.

Relation between the fading rate and storage period for emulsion of type *ET–6B* can be expressed approximately by an empirical equation of the form $D/D_0 = \exp(-c\sqrt{t})$. For type *ET–7A*, an empirical equation expressing a straight line such as $D/D_0 = 1 - kt$ was found adequate for all cases. However, they can also be expressed by a formula $D/D_0 = \exp(-c'\sqrt{t})$, which is the form suited for emulsions of type *ET–6B*. The advantage of expressing D/D_0 by a straight line is the proper fitting of the line to the experimental data through a wide range of storage times. Conversely, if expressed by the form of $\exp(-c'\sqrt{t})$, a better fitting of the curve to the experimental data could be obtained in a region of the longer storage time (greater than 40 days), but a worse deviation at the shorter storage time. This does not agree with LaPalme *et al.*[9]. A formula $D/D_0 = \exp(-c''t)$ has been tested, and it was found that it did not fit so well as the other two foregoing formulæ.

In investigating the relation between fading rate and relative humidities, the exposed plates were sealed in vessels of assigned vapour pressures of 7·00, 12·73, 20·68 and 25·46 mm mercury corresponding to relative humidities of 22, 40, 65 and 80 per cent respectively at 30° C. These plates were then stored under a constant temperature of 30° C for 93 days before processing. The processed plates, after counting grain densities, were found to have a relationship between the fading rate and relative humidities expressed by $D/D_0 = a\exp(-bH^2)$ (Fig. 2 and Table 2). In the formula expressing D/D_0, H is the relative humidity under which the plate was stored, a and b are constants.

In extrapolating the curves to zero humidities, values of $D/D_0 = 0\cdot94$ for type *ET–6B*, and 0·99 for type *ET–7A* were obtained. It can then be assumed that the main parameter on fading is due to oxidation of the development specks by atmospheric oxygen in the presence of water[5].

GEOPHYSICS

Origin of the Earth's Magnetic Field

FROM a knowledge of the mass of the Earth and its moment of inertia and from an analysis of seismic data, Bullen[1] has reconstructed a pressure-density curve for the Earth's interior. The outer core of the Earth is believed to be liquid since it does not transmit transverse seismic waves while the structure of the inner core is still in doubt. The entire core is believed to be predominantly iron.

According to Bullen, the interface between the inner and outer cores occurs at a depth of ~ 5,000 km corresponding to a pressure of $\sim 3\cdot3 \times 10^{12}$ dynes/cm², a temperature of ~4,000° K and a density of ~ 11·5 g/cm³ in the outer core and ~ 15·2 g/cm³ in the inner core. It is the purpose of this communication to suggest that the inner core may well be a new phase of iron in which two of the 3*p* 'argon core' electrons are transferred to the '3*d*–4*s*' band and that such a phase may account for the origin of the Earth's magnetic field.

That the foregoing values of density, pressure and temperature for the outer core are reasonable for iron comes from a knowledge of the compressibility of iron and its pressure dependence[2] $K = -(1/V)(\mathrm{d}V/\mathrm{d}P) = 5\cdot8 \times 10^{-13}\,(\mathrm{cm}^2/\mathrm{dyne}) \times (1 - 2 \times 10^{-13}\,P\,\mathrm{cm}^2/\mathrm{dyne}) = a(1 - bP)$ and an approximate value of the coefficient of volume expansion $\alpha = (1/V)(\mathrm{d}V/\mathrm{d}T) \simeq 80 \times 10^{-6}$/deg. This gives the density, ρ:

$$\rho(P,T) \sim \rho(0,0)\exp\{aP(1 - bP/2)\}\exp\{-\alpha T\}$$

where ρ(0) is the extrapolated density of liquid iron at $P = 0$, $T = 0$ leading to a value.

$$\rho(P,T) \simeq 11\cdot2\ \mathrm{g/cm^3}\ \text{(at the inner–outer core interface)}$$

in good agreement with Bullen's estimate. However, the density change in iron is only 3·5 per cent on melting so that the ~ 30 per cent change at the interface suggested by Bullen (11·5 g/cm³ versus 15·2 g/cm³) appears too large to attribute to normal solidification of iron in the inner core. On the other hand, the transfer of two of the 3*p* electrons to the '3*d*–4*s*' band would add two more electrons to the six bonding electrons (the two magnetic electrons are in anti-bonding states), and in analogy to the cases of the rare earth metals, cerium, europium and ytterbium, this would change the atomic volume approximately in proportion to the number of overlapping electrons. In iron this new high-pressure phase would correspond to a density change of ~ 25 per cent.

That the transfer of one or two electrons from the 3*p* shell to the overlapping '3*d*–4*s*' band is energetically feasible comes from an estimate of the band-width and the one electron energy eigen values of the 3*p* electrons. Because of the large overlap of the '3*d*–4*s*' electrons at these high pressures we can use free electron theory to give an approximate value of the band-width and this gives ~ 55 eV for the inner core as compared to 69 eV for the Hartree–Fock one electron 3*p* energy[3]. (The X-ray absorption edge in metallic iron corresponding to a transition from the 3*p* level to the Fermi level occurs at 53 eV.) (In analogy to the rare earth metals, thulium, ytterbium and lutecium, I suggest that two rather than one electron will be transferred from the inner closed shell although this point is not critical to my argument.)

Because of the very strong spin orbit coupling, the remaining four electrons in the 3*p* shell will probably couple according to Hund's rule leaving two unpaired electrons with $L = 1$, $S = 1$, $J = 2$. In order to estimate the Curie temperature of this new phase we need to estimate the exchange energy. While such a straightforward calculation is beyond the present capabilities of solid state physics, an approximate value can be obtained relative to the ordinary form of ferromagnetic iron for which we have experimental values of the exchange energy[4]. Since the exchange energy arises from the overlap of the band electrons with the unpaired atomic-like electrons we wish to estimate the exchange integral:

$$J \alpha \left| \int \psi_A(r_1)\psi_B(r_2) \frac{e^2}{r_{12}} \psi_A(r_2)\psi_B(r_1) d\tau \right|^2 / E_F \qquad (1)$$

where the subscript A denotes the unpaired atomic-like electron wave function and the subscript B the overlapping band electron wave function and E_F is the Fermi energy. For the normal ferromagnetic form of iron these are the unpaired $3d$ and the '$3d$–$4s$' band electrons respectively, while for our postulated high-pressure form of iron these are the $3p$ and the '$3d$–$4s$' band electrons respectively. Since the overlapping electrons at the bottom of the band in iron are extended quite far radially (Wood, J. W., unpublished results) we can assume ψ_B is constant throughout the atomic cell for both the normal and high-pressure phases. This term alone would lead to a ratio of ~ 6·5 for the values of J in the high-pressure and normal phases while the Fermi energy in the denominator (55 eV versus ~ 10 eV) reduces this to ~ 1·2. This leaves the evaluation of the r_{12} term for the unpaired $3p$ and $3d$ electrons respectively, and this must surely be greater for the former since they are more compressed radially. It is estimated that their contribution to J would lead to a ratio approximately of the order of their one electron energies (– 5·3 Rydbergs versus – 1·3 Rydbergs) or about a factor of 4. This roughly gives an overall factor of 4 for the ratio of J in the high-pressure and normal phases or a value of 0·04 eV for the high-pressure phase. (If we apply equation 1 to the normal cases of ferromagnetic iron and gadolinium, where in the latter case ψ_A refers to the $4f$ electrons, one obtains a ratio of ~ 40 for the J values as compared with the observed value of ~ 50.)

From statistical mechanics a close-packed structure with nearest neighbour exchange interactions[4] ($S = 1$) has a value of $J/kT_c = 0·08$, leading to an estimated value of the Curie temperature of our high-pressure form:

$$T_c \simeq J/0·08k = 5{,}500° \text{ K}$$

which is well above the inner–outer core interface temperature of ~ 4,000° K.

If this crude order of magnitude estimate is correct there are several consequences of note:

(1) If the planets contain cores similar in composition to the Earth only those of mass approximately equal to or greater than the Earth would develop sufficient gravitational pressure to create the high-pressure magnetic phase. Thus we would expect no magnetic field on Mercury, Mars, Venus and the Moon, but would expect magnetic fields on Uranus, Neptune, Saturn and Jupiter.

(2) If the inner core were saturated (a single magnetic domain) the magnetic field at the Earth's surface would be about ~ 150 gauss. The observed value of ~ 1 gauss is thus typical of the residual magnetization of an unmagnetized piece of iron.

(3) Magnetostrictive effects (spin-orbit coupling) can cause variations in the magnitude and direction of the Earth's magnetic field depending on the variation of the distribution of pressure on the surface of the inner core. Because the anisotropy energy is small compared with the compressional energy only small changes in pressure are necessary to effect changes in magnetic domain orientation.

(4) Inasmuch as static pressures of ~ 0·5 × 10^{12} dynes/cm^2 have been reached in the laboratory[5], it is probable that materials and techniques will improve sufficiently to reach this suggested critical pressure of ~ 3·5 × 10^{12} dynes/cm^2 for the onset of the high-pressure magnetic phase of iron. Thus this hypothesis is probably capable of laboratory refutation.

GEOCHEMISTRY

Evidence of an Extraterrestrial Origin for Some Organic Constituents of Meteorites

The presence of organic matter within samples of carbonaceous chondrites is now well established[1–3]. However, it has been suggested from several sources that considerable terrestrial contamination of these meteorites may have occurred and that the organic matter is not indigenous. The experiments reported in this communication were conducted to determine whether the isotopic composition of the meteorite organic matter afforded any evidence regarding the origin of the compounds.

Samples of Orgueil, Murray, Mokoia and Haripura meteorites were extracted separately for 6 h in a Soxhlet apparatus with a 9 : 1 benzene–methanol mixture. The solvent was evaporated from the extract and the isotopic composition determined of the hydrogen, carbon and sulphur of residues from each meteorite by mass spectrograph. Results of these determinations are shown in Table 1.

Table 1. Isotopic Composition of Meteorite Organic Matter

Meteorite	Deuterium (%)	Carbon-13 ($^0/_{00}$)	Sulphur-34 ($^0/_{00}$)
Orgueil	+ 27·5	– 10·1	+ 3·14
Murray	+ 8·4	– 4·0	+ 2·86
Mokoia	+ 21·2	– 17·9	+ 1 09
Haripura	– 1·5	– 3·1	+ 2·51

Standards. Deuterium and carbon, Craig (ref. 6); sulphur, Thode *et al.* (ref. 7).

A comparison of these isotopic values with those for non-carbonaceous meteorites and for various terrestrial materials[8] reveals that the organic matter from three of the carbonaceous chondrites shows a considerable deuterium enrichment, while the carbon shows a lack of carbon-13 similar to terrestrial biogenic material. The small enrichment of sulphur-34 is the opposite fractionation to that occurring in sulphur bacteria and terrestrial inorganic processes. It is apparent that the isotopic composition of meteorite organic matter is quite unlike that of any terrestrial substances.

The evidence presented here is indicative of an extraterrestrial origin for a major fraction of the organic constituents of carbonaceous chondrites.

I thank the Curator of the Wanganui Museum, Dr. W. A. Watters, of the New Zealand Geological Survey, Dr. E. P. Henderson, of the Smithsonian Institution, and the Director of the Geological Survey of India for gifts of meteorite samples.

METALLURGY

Destruction of the Widmanstatten Structure in Iron Meteorites by Laboratory Heat Treatment

A KNOWLEDGE of the response of iron meteorites to heat treatment is necessary for the understanding of such specimens as Kamkas[1] which appear to have suffered partial destruction of their Widmanstatten structures by cosmic heat treatment. Kasé[2] has published evidence to show that for the medium octahedrite Sacramento Mountains the nickel-rich taenite is still clearly visible after a heat treatment of 20 min at 1,000° C or 3 min at 1,200° C. Even after 4 min at 1,300° C there remains a faint trace of nickel enrichment which marks the previous location of a taenite area.

In the work recorded here more lengthy heat treatments were conducted on small (0·5 × 0·5 × 1·0 cm) fragments taken from a specimen of Canyon Diablo which is known to contain cohenite. In each case duplicate specimens were sealed in evacuated silica capsules which were heated to the maximum temperature over a period of three days and afterwards cooled to room temperature over three days. The period of holding at maximum temperature was 2 days at 1,000° C and 3 days at 1,100° C or 1,180° C. Experiments with specimens of this size do not correctly reproduce the conditions in a massive meteorite since at 1,100° C and 1,180° C it was found that all the schreibersite melted to eutectic and exuded along the original kamacite phase boundaries to produce a layer of phosphide-rich liquid on the outer surface of the specimens. At 1,000° C exudation was incomplete and the resolidification of liquid veins within the specimen produced structures similar to that illustrated by Perry[3]. With increasing temperature the phosphide eutectic, which had left the solid by way of grain boundaries in the original structure, showed an increased tendency to re-enter the solid by way of the new γ-grain boundaries which were formed by heat treatment of the kamacite. Macro- and micro-scopic observations were made on etched sections at locations away from the regions of grain boundary penetration. Macroscopic examination of the etched sections with the aid of a hand-lens revealed the recognizable remains of taenite ribbons after all heat treatments. Microscopic examination showed that the original kamacite regions had changed to a duplex arrangement of ragged ferrite and small carbide crystals. It was possible to detect the boundaries of the γ-grains from which the ferrite-carbide aggregate formed on cooling. The microstructure of the taenite regions showed a greater variation with heat treatment temperature. After the 1,000° C heat treatment the taenite still maintained a distinct boundary and was at no place crossed by the new generation of γ-grain boundaries; suggesting that the taenite had maintained its complete integrity at the heat treatment temperature. The taenite itself was characterized by a fine precipitate of non-metallics at the centre and an indistinct acicular structure at the edge.

After the 1,100° C heat treatment the taenite boundary was less sharp and was demarked by acicular (bainitic) transformation product. No precipitate was observed within the taenite and the presence of new generation γ-grain boundaries within the taenite was rare.

The 1,180° C heat treatment resulted in a coarse pattern of acicular transformation product within which the pattern of new generation γ-grain boundaries was continuous with that in the kamacite, indicating that at 1,180° C the taenite had lost its physical identity as a separate crystal but had retained a sufficiently different chemical composition to reveal itself by the production of acicular transformation product on cooling.

Less detailed examination of carbide-free specimens heated to 1,000° C and 1,100° C revealed a 'watery' appearance in the taenite without acicular transformation product. The acicular product may thus be tentatively identified as a carbon containing bainite.

Topography of Kish Crystals and the Effect of Oxidation in Air

DETAILED studies have been reported recently on the production of etch pits in purified Ticonderoga natural graphite crystals as a result of oxidation in oxygen in the temperature range 700°–870° C[1,2]. Others have also been concerned with the effect of oxidation on the topography of natural graphite[3–6]. In this communication, the effect of oxidation on the topography of purified kish crystals is considered.

Kish is a waste product which forms on the surface of molten iron of high carbon content during the manufacture of steel. It is carbon which has been taken into solid solution with the iron and is afterwards evolved when the iron cools. Kish particles are large and flaky, resembling large particles of natural graphite. Walker and Imperial[7] have previously shown that purified kish has the same interlayer spacing as Ceylon natural graphite, indicative that it has a large crystallite size and essentially complete three-dimensional ordering.

The kish used in this investigation was purified by boiling alternately in hydrochloric acid and hydrofluoric acid (or in some cases just boiling in hydrochloric acid), followed by repeated washings in distilled water, and drying in a vacuum oven. Its structure has been further studied by transmission electron diffraction, using 50-kV electrons having a beam width of 10μ. The diffraction pattern (Fig. 1) is characteristic of a material of large crystallite size and a high degree of preferred crystallite orientation (essentially a mosaic single crystal).

The basal plane (000*l*) surfaces of the kish were studied by light microscopy. Typical micrographs of the unoxidized kish are shown in Figs. 2 and 3. In Fig. 2, the twin planes are readily distinguished as the striations running parallel to one another or intersecting at 60° (ref. 8). The presence of impurities on the basal plane, following treatment with hydrochloric acid only, is clearly in evidence. On a very significant portion of the surface, large hexag-

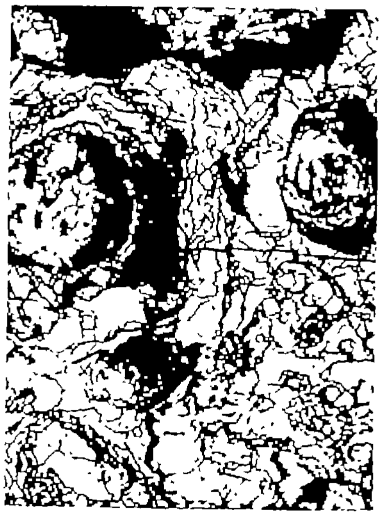

Fig. 6. Roughly hexagonal holes produced by rapid attack of air at 850° C on hexagonal stepped growths of purified kish. (× c. 200)

onal stepped growth features are in evidence (Fig. 3). It is suggested that the growth steps within these features arise from a piling-up of a large number of clockwise and counterclockwise spiral growth steps of molecular dimensions[9,10] (the spirals being invisible on our photographs). A substantial concentration of impurity nucleating centres from which such screw dislocations and spiral growth of graphite could occur might well be expected, considering the origin of kish.

Kish crystals were oxidized in air (1 atm.) at 850° C. Fig. 4 shows the development of a large number of hexagonal pits oriented parallel to each other and parallel to the twin lines, as previously discussed[1]. Figs. 5a and b show the results of coalescence of pits during a more advanced stage of oxidation. The shapes of the holes are reminiscent of those suggested by Ubbelohde, when considering defects in graphite[11].

In general, it is found that the large hexagonal stepped growths are attacked at an enhanced rate. Fig. 6 shows the result of exposure of such growths to air at 850° C for only about 5 min. Large, roughly hexagonal holes are produced, in contrast to the relatively minor attack on other portions of the surface. However, it is not possible to decide on the basis of this result whether the presence of dislocations or the possible concentration of impurities at dislocations is of primary importance in the production of pits in the basal plane. As discussed previously[8], uncertainty will remain until oxidation studies are carried out on ultra-high purity graphite of known dislocation content.

CHEMISTRY

Reaction of Platinum and Boron under Pressure

DURING some high-temperature–high-pressure experiments involving boron, a new phase appeared in the X-ray diffraction patterns of the samples. This phase was traced to the reaction of boron and the platinum foil used to encapsulate the sample between the chrome carbide pistons of a Griggs and Kennedy simple squeezer[1]. Since platinum foil is a standard technique of sample enclosure for this type of experiment, it was decided to investigate the *P–T* phase diagram of this reaction so that it would not cause difficulty when encountered again.

At about the time this work was finished two papers came to our attention bearing on this problem and have prompted us to publish our results. The first was a paper by Jamieson and Lawson[2] in which they referred to the formation of a new phase from boron at 600° C and 40 kilobars (kb). No mention was made of platinum and, in reply to a letter of ours, Prof. Jamieson confirmed our suspicion that platinum foil was in contact with the boron. He was also kind enough to send us X-ray photographs of his samples. It will be seen that this new phase lies just to the right of the boundary between boron and platinum and platinum boride (Fig. 1).

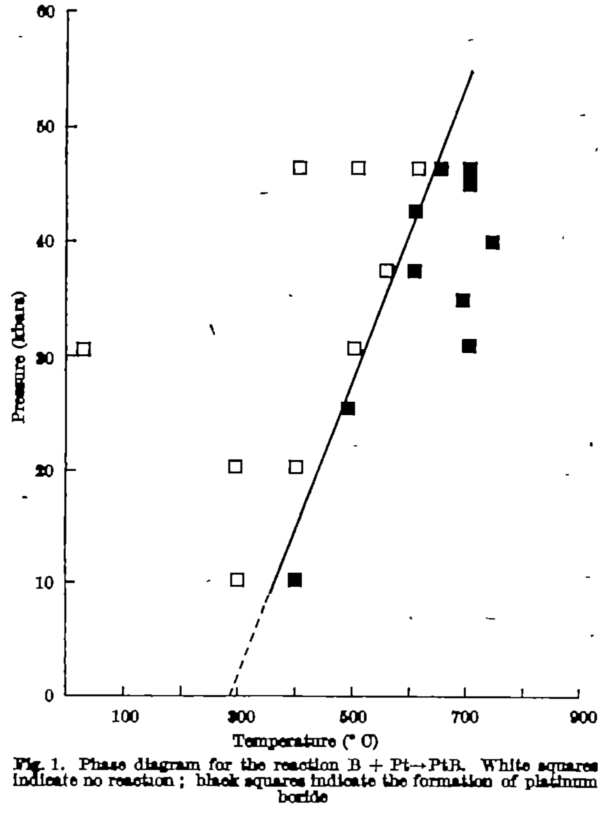

Fig. 1. Phase diagram for the reaction B + Pt→PtB. White squares indicate no reaction; black squares indicate the formation of platinum boride

A recent paper by Aronsson *et al.*[3] has allowed us to identify the platinum boride as PtB (space group $P6_3/mmc$, $a = 3{\cdot}36$ Å, $c = 4{\cdot}06$ Å), and to confirm the identity of Jamieson's material with our platinum boride. There are a few weak X-ray diffraction lines not due to PtB which can be attributed to B_2O_3 and the original boron.

The slope of the curve shown in Fig. 1 was found to have a value of $dP/dT = 133$ bars degree^{-1}. It is of interest to note that Strong and Bundy[4] found the value of dP/dT for the melting point of platinum to be 140 bars degree^{-1}.

The X-ray diffraction results are listed in Table 1. We are grateful to Prof. Jamieson for permission to examine his films and publish the results.

Electrical Storage and Hydrogen Transfer between Electrodes of Palladium and Palladium Alloys

ELECTRODES of palladium and palladium alloys can absorb large volumes of hydrogen. In general, the solid hydrides retain excellent electrical conductivity and are not severely embrittled or disrupted. For pure palladium, and for many alloys, the relationships between electrode potential *E* (with respect to a hydrogen reference electrode in the same solution) and hydrogen content (written here, Fig. 1, as the ratio, H/Me, of hydrogen atoms to the total number of metal atoms) exhibit 'plateau' regions—over which α- and β-phase hydrides co-exist—where *E* is relatively invariant ($E_{\alpha\beta}$). Over such 'plateau' regions, hydrogen transfer should, in principle, occur at a constant rate when connexion is made between an alloy and palladium or between two alloys. However, polarization[1] would be expected to occur rapidly if the diffusion of hydrogen within the electrodes were not sufficiently fast for the concentration of hydrogen at the surfaces to be continuously representative of the ranges of H/Me corresponding to the plateaux. The following experiments serve to illustrate what may be observed in practice.

The *E*–H/Me relationships, at 25° C, for palladium and two selected alloys[1–3] are shown in Fig. 1, where full lines indicate relationships which apply when hydrogen is being absorbed and broken lines approximate to relationships when hydrogen is desorbed relatively slowly. Each electrode was about 15 cm of 0·0274-cm diam. wire (about 0·1 g). The electrolyte was 1·0 N hydrochloric acid, thermostatted at 25° C and saturated with argon. All electrodes had been palladized to confer a low surface impedance[1,4] and prior to an experiment each had been caused[1] to absorb hydrogen until $E \sim 50$ mV (A, B and C in Fig. 1).

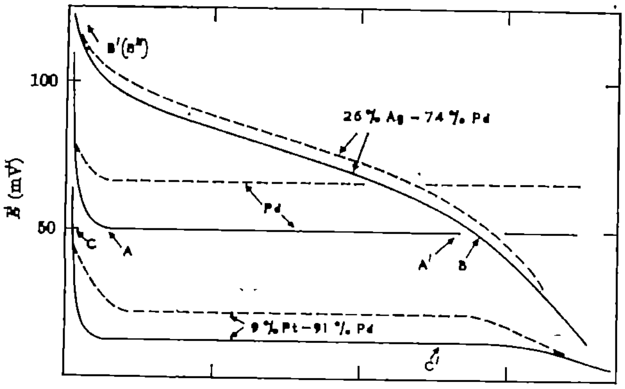

Fig. 1

In the first experiment (I) an E.M.F. of 200 mV was first applied between palladium and the palladium/silver alloy so that hydrogen was transferred (Fig. 1) from Pd/Ag/H ($B \rightarrow B'$) to Pd/H ($A \rightarrow A'$). The resultant current flow was measured (Fig. 2) by recording the potential drop across a 10 Ω resistor in series. On development of a polarizing potential of about 140 mV, the discharge of the cell, through the 10 Ω resistor, was then also recorded. The palladium/platinum alloy was combined with the palladium/silver alloy in the second experiment (II), which was carried out with the same procedure, so that, when charging, the hydrogen was likewise transferred from Pd/Ag/H ($B \rightarrow B''$) to Pd/Pt/H ($C \rightarrow C'$). Throughout both experiments the apparent internal resistance of the cells was approximately 20–30 Ω.

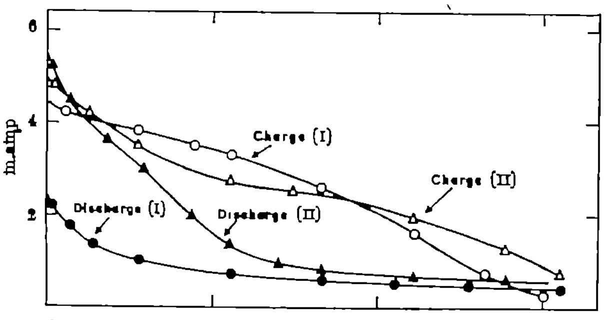

Fig. 2

During discharge over the plateau regions, the E.M.F. of the cells only corresponds, even ideally, to the differences between the 'absorption' value of $E_{\alpha\beta}$ for the electrode absorbing hydrogen and the 'desorption' value of $E_{\alpha\beta}$ for the desorbing electrode. However, Fig. 2 illustrates an improvement in terms of rapid discharge, which follows as a consequence of increasing this difference. Unfortunately, the rather restricted and imperfectly invariant plateau, illustrated in Fig. 1, for the 26 per cent silver – 74 per cent palladium alloy represents close to the highest 'plateau' values which have been reported at 25° C for the alloy systems so far investigated[1]. On the other hand, palladium alloys are available with lower values of $E_{\alpha\beta}$ (25° C); and somewhat higher rates of discharge than illustrated in Fig. 2 have been obtained from a similar cell composed of a 12 per cent platinum – 88 per cent palladium alloy[1] and the palladium/silver alloy. However, as E decreases the loss of stored hydrogen by diffusion of molecules away from the electrode becomes increasingly significant[5-7] since, for specimens with low surface impedance, E is related to the hydride vapour pressure, p by the relationship E (volts) $= -0{\cdot}029 \log p$.

We thank the International Nickel Co. (Mond), Ltd., for providing the palladium alloys.

A Carbon Isotope Effect in the Decarboxylation of the Anisoyloxy Radical

There have been several reports of carbon isotope effects during the decarboxylation of dibasic carboxylic acids such as malonic acid[1]. Similar effects would be expected in the radical reaction:

$$R.CO.O. \rightarrow R. + CO_2$$

The rate at which the radical $R.^{14}CO.O$ dissociates is expected to be less than that for the corresponding reaction of the radical $R.^{12}CO.O$.

If aroyloxy radicals, for example the anisoyloxy radical, are generated in a medium containing reactive substances, there is competition between the processes:

$$CH_3.O.C_6H_4.CO.O. \rightarrow CH_3.O.C_6H_4. + CO_2 \quad \text{velocity constant} = k_1 \quad (1)$$

$$CH_3.O.C_6H_4.CO.O. + X \rightarrow \text{stable products} \quad \text{velocity constant} = k_2 \quad (2)$$

X may be a molecule with a labile hydrogen atom, in which case the stable product is anisic acid, or an unsaturated compound which captures the anisoyloxy radical to give another radical such as $CH_3.O.C_6H_4.CO.O.CH_2.CHX$. The fraction ($f$) of radicals losing carbon dioxide is equal[2] to $k_1/(k_1 + k_2[X])$. The velocity constant k_2 cannot be affected by introducing a heavy atom of carbon into the anisoyloxy radical. Any change in k_1, resulting from isotopic substitution, would alter the value of f; this would result in a change in the amount of carbon dioxide produced in a system in which a certain number of anisoyloxy radicals are generated.

Anisoyloxy radicals can be generated at a convenient rate by the decomposition of di-anisoyl peroxide in benzene at 60° C; under these conditions, about 50 per cent of the radicals dissociate to give carbon dioxide. The production of carbon dioxide by reaction (1) can be followed[3] by the method of isotope dilution analysis using peroxide labelled with carbon-14 at its carboxyl groups as the source of anisoyloxy radicals. The specific activity of the carbon dioxide produced during the decomposition is calculated from that of the original peroxide. If the expected isotope effect operates in reaction (1), the specific activity of the carbon dioxide must be less than the calculated value, and consequently low values must be obtained for the yield of carbon dioxide.

The weight of carbon dioxide formed during the decomposition of unlabelled di-anisoyl peroxide can be found by isotope dilution analysis; in this case, however, labelled carbon dioxide is added to the system after completion of the reaction. This procedure avoids interference from isotope effects and should lead, therefore, to true values for the yields of carbon dioxide.

Full details of the experimental procedure and the results will be published later; the first results show clearly, however, that the expected carbon isotope effect does operate during the dissociation of the anisoyloxy radical. Solutions of the peroxide in benzene (2·5 g/l.) were degassed and kept at 60° C for 48 h; during this time about 73 per cent of the peroxide decomposed. Yields of carbon dioxide were determined by both methods of isotope dilution analysis. By the technique involving ^{14}C-di-anisoyl peroxide, the weights of carbon dioxide produced from 1 mg of peroxide present originally were 0·0846, 0·0847, 0·0856 and 0·0855 mg; the mean value is 0·0851 mg. From experiments involving unlabelled peroxide, the weights of carbon dioxide were found to be 0·1024, 0·0940, 0·0851, 0·1084 and 0·1230 mg with a mean value of 0·1026 mg.

Polarizability Theories of Polynucleotide Hypochromism

Bolton and Weiss have recently given[1] expressions for the decrease in optical absorption (hypochromism) of a classical oscillator caused by the polarizability of identical neighbouring oscillators, and suggest their theory explains the hypochromism of helical polynucleotides. Their result is surprising, since it violates the sum rule for oscillator strengths.

Bolton and Weiss consider the classical interaction of each oscillator with the incident electric field and the additional field caused by the induced moments of the other oscillators. For their dimer model with two parallel one-dimensional oscillators coupled in this way, the complex polarizability of one of the oscillators along its polarization direction can readily be verified (by insertion in the equations of motion) to be:

$$\alpha = [3e^2f/m(x^2 + z^2\omega^2)]\,[x - iz\omega] \qquad (1)$$

where e and m are the charge and mass of an electron, f is the oscillator strength, ω is the circular frequency of the incident light, z is an intrinsic damping frequency and x is related to the resonance frequency ω_0 of an isolated oscillator by:

$$x = \omega_0^2 - \omega^2 - 3ke^2f/m \qquad (2)$$

Here, k is a coupling parameter dependent on the intergroup distance d; k equals $-1/d^3$ for transversely oriented oscillators and $2/d^3$ for longitudinally oriented oscillators. When k equals zero, (1) gives the polarizability of an isolated oscillator.

The molar extinction coefficient ε at circular frequency ω is given by[2]:

$$\varepsilon = -\frac{4\pi N\omega}{2303\,c}(Im\ \alpha/3) = \frac{4\pi Ne^2f}{2303cm}\ \frac{z\omega^2}{(x^2 + z^2\omega^2)} \qquad (3)$$

(N = Avogadro's number; c = velocity of light.) Thus the absorption curve for any value of the coupling parameter k has the same maximum value and the same width (z) at half maximum absorption, but the circular frequency of maximum absorption is shifted from ω_0 by approximately $-3ke^2f/2\omega_0m$. (A quantum mechanical analogue is the shift in the spectrum of parallel degenerate transitions due to exciton strong coupling[3].) It is clear that the integrated intensity (the area under the ε versus ω curve) cannot change, and thus there is no hypochromism. Bolton and Weiss's expressions give the absorption at frequency ω_0, which is not the frequency of maximum absorption when the absorption curve has shifted.

Hypochromism can be explained by a similar local field treatment, however, when the polarizability of non-absorbing oscillators is taken into account. As will be shown, the results are exactly equivalent to the quantum mechanical perturbation theory derivations of Tinoco[4,5] and Rhodes[6], which obey the oscillator strength sum rule[6] and which (contrary to statements of Bolton and Weiss[1], and also of Nesbet[7]) can account for the observed hypochromism of polynucleotides without a change in the shape or position of the absorption band (through exciton weak coupling[3]).

Briefly, the treatment consists of calculating the net local field $\mathbf{E}$ at a monomer group i which contains the one-dimensional oscillator under investigation; the oscillator is polarized along the monomer-fixed unit vector e_{ia} and has resonance frequency ν_a. An oscillator in a nearby group j (which can be another monomer or a solvent molecule), having a resonance frequency ν_b (different from ν_a) and oscillator strength f_b and polarized along unit vector e_{jb}, has an in-phase polarizability at frequencies close to ν_a given from (1) by:

$$\alpha_{jb} = 3e^2f_b/4\pi^2m(\nu_b^2 - \nu_a^2) \qquad (4)$$

If the incident field is $\mathbf{E}_0 = Ae\cos(2\pi\nu t)$, where ν is close to ν_a, then the field at monomer i due to the induced point dipoles of all nearby groups j is:

$$\mathbf{E}' = -\sum_{j\neq i}\sum_{b} \alpha_{jb}r_{ij}^{-3}\,[e_{jb} - 3(e_{ij}.e_{jb})e_{ij}]e.e_{jb}A\cos(2\pi\nu t) \qquad (5)$$

where r_{ij} is the intergroup distance and e_{ij} is a unit vector along the line joining the two groups.

The rate of energy absorption by monomer i at a given frequency ν is proportional to[8]:

$$[\,(\mathbf{E}.e_{ia})/\cos(2\pi\nu t)\,]^2$$

This expression must be averaged over random directions of e relative to e_{ia}. Using the relations:

$$[\,(e.e_{ia})^2]_{av} = 1/3$$
$$[\,(e.e_{ia})\,(e.e_{jb})\,]_{av} = (1/3)e_{ia}.e_{jb} \qquad (6)$$

one finds that the ratio C of the integrated intensities for the rigid polymer and for the randomly oriented monomers is:

$$C = \{[\,(\mathbf{E}_0 + \mathbf{E}').e_{ia}]^2\}_{av}/\,[(\mathbf{E}_0.e_{ia})^2]_{av}$$
$$\approx 1 - 2\sum_{j\neq i}\sum_{b}\alpha_{jb}r_{ij}^{-3}\,[e_{ia}.e_{jb} - 3(e_{ij}.e_{ia})\,(e_{ij}.e_{jb})\,] \times e_{ia}.e_{jb} \qquad (7)$$

Finally, inserting (4) in (7), one obtains:

$$C = 1 - \frac{3e^2}{2\pi^2m}\sum_{j\neq i}\sum_{b}\frac{f_b}{(\nu_b^2-\nu_a^2)r_{ij}^3}$$
$$\times\ [e_{ia}.e_{jb} - 3(e_{ij}.e_{ia})\,(e_{ij}.e_{jb})\,]e_{ia}.e_{jb} \qquad (8)$$

which is identical to the expressions given by Tinoco[4] and Rhodes[6].

Quantitative applications of (8) to the hypochromism of polynucleotides have been made[4,6,9,10]. If the absorbing oscillators are of low frequency ($\nu_a < \nu_b$) and are longitudinally oriented (for example, $n \rightarrow \pi^*$ transitions in helical polynucleotides), the spectrum is expected to be hyperchromic[9], not hypochromic as predicted by Bolton and Weiss.

A more detailed description of this treatment, with applications to solvent effects on solute spectra, is being prepared for submission elsewhere.

We have read with interest the preceding communication but we have the impression that DeVoe has misunderstood to some extent both Nesbet's and our work. In the first part of his communication, DeVoe refers to the well-known classical equation for a pair of coupled oscillators with regard to a given direction of the electric field. However, in our treatment of the dimer, it is explicitly stated that our equation refers to isotropic oscillators and averaged over all directions of the electric field vector. We have, in fact, calculated the absorption coefficient for the frequency corresponding to the maximum absorption in the monomer. However, in the case under consideration, this also corresponds to the frequency of maximum absorption in the dimer. In fact, the absorption due to the longitudinal dipole oscillations in the dimer is shifted in frequency (without change of intensity or width) and that due to the transverse oscillations is shifted in the opposite sense, but the mean frequency for the isotropic case (one longitudinal plus two transverse polarizations) is not changed. In the hypothetical case of a very narrow band, this would appear as a splitting, or if the monomer band is already visibly split this would result in opposite displacements of the components. In the cases under consideration we were concerned with a situation corresponding to nucleic acid, where the absorption bands would be too broad (half-width ~ 300 Å) for this splitting to be observed. Thus the net effect here is a reduction of the absorption at the peak, which, however, should be compensated by some additional broadening elsewhere so as to preserve the total oscillator strength; there is therefore no violation of the sum rule.

In the nucleic acids there are four different monomer units, the light absorption of which varies quite significantly around 2600 Å, each unit having two transitions polarized perpendicular to each other. It is clear, therefore, that any theory which is based on very few assumptions can only be regarded as a first approximation for such a complex structure.

The importance of the sum rule in these situations has been emphasized on a previous occasion[1], although in the later paper it was suggested that it might possibly not hold in this case. However, I am reassured now that it is valid and remains so even if the small retardation effects due to the finite distance between the monomer units are taken into account. In any event, neither our calculations nor Nesbet's treatment do, in fact, imply a violation of the sum rule for the oscillator strength. Nesbet[2] has given a quantum mechanical treatment for the hypochromic effect. This takes as its basis that in quantum mechanics the ground-state of the dimer contains an admixture of the state in which two units are excited due to the interaction between the virtual dipole moments of the units, which is also responsible for the van der Waals force. This can be interpreted in such a way that as a result of this there exists a radiative transition from the ground state to the state in which three units are excited, corresponding to the frequency 3ν, if ν is the frequency of maximum absorption of the single unit. This frequency, 3ν, is likely to be outside the region normally accessible to spectroscopic observations (in the case of the nucleic acids it would be around 900 Å) and it would, in general, be masked by absorption processes of a different kind situated in this region. This transition would use up some of the oscillator strength of the polymer, so that the fundamental absorption in the ultra-violet is reduced; there is, therefore, here again, no violation of the sum rule.

In the second part of his communication, DeVoe suggests a theory of hypochromism on the basis of our treatment but taking into account the non-absorbing oscillators present in the system. Such a treatment, although formally correct, raises doubts as to its significance both on theoretical and experimental grounds. DeVoe's statement that such an interaction is without change in position of the absorption band is not correct; in fact, the reduction in oscillator strength to compensate for that which would appear near the resonance frequency of the particular (non-absorbing) oscillator is always associated with a shift in frequency. Moreover, taking, for example, a transition at 2000 Å, as has been suggested, there is no obvious reason why this should only be significant in the polymer and not in the monomer, as the monomer unit is itself a relatively very large and complex unit which absorbs quite strongly at 2000 Å.

Therefore, it is not at all obvious, without making very special assumptions, why such a transition in the polymer should be more effective compared with a transition in the same spectral region within the same monomer unit. Moreover, as the interaction between oscillators decreases relatively rapidly with increasing distance, one should expect that an interaction within the same monomer would be more effective. This model would not therefore explain, without very special assumptions, the difference between the monomer and the polymer in any convincing way. DeVoe's treatment of this effect is purely qualitative, as indeed it has to be because the effect must depend on some definite assumptions regarding the number and frequencies of the non-absorbing oscillators which are taken into account, so that the whole treatment would be based on more or less arbitrarily chosen parameters.

Finally, it should be pointed out that in undenatured nucleic acid any hyperchromism at 2000 Å, or for that matter at any other wave-length in the ultra-violet region, as required by this theory, is not supported by experimental evidence.

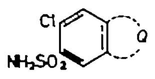
BIOCHEMISTRY

5-Chloro-2-*cyclo*hexyl-1-oxo-6-sulphamoyl Isoindoline : a New Diuretic

The introduction of chlorothiazide (Table 1, I) in 1957 marked a major advance[1] in the search for improved non-mercurial diuretics. Its advent was followed by a succession of more potent derivatives[2]. Clinically, however, apart from the size of dose, all these derivatives produced a similar therapeutic response[3]. One of the few disadvantages of these compounds is the loss of potassium which occurs concurrently with the excretion of sodium ions and can necessitate the administration of potassium supplements.

The initial object of the present research was therefore to find a compound which would cause relatively less loss of potassium than chlorothiazide. On the available evidence it seemed to us that such a compound was more likely to be found among analogues which represented major structural modifications to the heterocyclic ring of chlorothiazide (I), rather than among further substitution derivatives of chlorothiazide itself. Accordingly, we synthesized the structures (III)–(VIII) (Table 1), in which the endocyclic sulphonamide group of (I) was replaced by a number of markedly different groupings.

Table 1



Compounds with diuretic activity in the rat		Compounds inactive as diuretics in the rat	
Compound	Value of *Q*	Compound	Value of *Q*
(I) Chloro- thiazide		(V)	(II)		(VI)	(III)		(VII)	(IV) M and B 8430		(VIII)	
Diuretic activity was first found in the benzothiatriazine analogues (II) of chlorothiazide, but it soon became evident that this new class was unlikely to provide the compound we sought. In the rat, diuretic activity of the compound (II; $R = CH_3$) equalled that of chlorothiazide, but the ion excretion pattern showed no relative advantage in regard to potassium loss. Changing the substituent R to benzyl[4] diminished activity. Reduction of the 3 : 4-double bond in (II; $R = CH_3$) to give analogues of hydrochlorothiazide was not chemically feasible.

The phthalimides[5] (III), on the other hand, were more promising chemically. Modification of the substituent R presented few difficulties, and of 27 compounds prepared the most active were those in which R = *cyclo*alkyl, particularly (III; R = *cyclo*hexyl), a compound found to be 6 times as active as chlorothiazide in the rat.

The related compounds (V), (VI), (VII) and (VIII) were inactive as diuretics. However, reduction of (III; R = *cyclo*hexyl) with tin and hydrochloric acid afforded the corresponding isoindoline[6] (IV), which proved to be markedly more potent than the starting material.

This compound (IV; M and B 8430), which formed non-hygroscopic colourless prisms, m.p. 266°–268°, soluble in water only to the extent of 16 mg/l. at 25°, was made the subject of detailed pharmacological study.

Assays in the rat and dog showed that M and B 8430 was about 100 times as active as chlorothiazide on oral administration. The onset and duration of the diuresis, and the excretion of both sodium and potassium ions, induced by equipotent doses of M and B 8430 and chlorothiazide, were very similar.

From experiments on the excretion of water, sodium, potassium and chloride ions in the rat and dog, it appeared that M and B 8430 inhibited tubular reabsorption of sodium since it caused an increased concentration of sodium in the urine, which was correlated with increase in dose, whereas water excretion, though dose dependent, was very much more variable. There was no change in glomerular filtration rate as measured by creatinine clearance in the dog. The compound was not a potent carbonic anhydrase inhibitor *in vitro*.

In chronic toxicity experiments in rats, dogs and monkeys over a period of 3 months, no gross abnormalities were found, nor was there any evidence of marked changes in the tissues at post-mortem examination. Further detailed, comparative toxicity investigations are being carried out.

The results of some preliminary clinical trials[7,8] have confirmed the diuretic effect of M and B 8430, the therapeutic dose being about 50 mg a day. The compound appears to have a potency and duration of action similar to those of hydrochlorothiazide. The compound was well tolerated. Relative potassium excretion was similar to that produced by an equipotent dose of chlorothiazide.

We thank Dr. A. K. Armitage and Mrs. J. E. Boswood for their collaboration in some of the early pharmacological experiments, and Mr. K. F. Rivott for the results of toxicity experiments.

Constitution of the Cross-linkages in Elastin

Elastin is insoluble in all reagents except those which break peptide bonds, and when wet the protein behaves as a typical rubber-like solid[1]. These characteristics, together with the swelling properties, are consistent with the view that elastin can be regarded as a cross-linked polymer gel containing long peptide chains randomly crumpled and held laterally at intervals by strong chemical bonds[2]. In an attempt to isolate small regions of the peptide network containing the cross-links, Thomas and Partridge[3] degraded the protein by use of a succession of proteolytic enzymes followed by amino- and carboxypeptidases. The product consisted of amino-acids and small peptides together with a fraction of higher molecular weight. This fraction was isolated and was found to be bright yellow in colour with the blue-white fluorescence characteristic of elastin fibres.

Amino-acid analysis, after acid hydrolysis, showed that the purified fluorescent compound contained about 40 per cent of its weight as glycine, proline and alanine approximately in the molar ratio 1 : 1 : 2, but small quantities of other amino-acids were also present. From the content of proline and glycine the minimum molecular weight of the fluorescent peptide was near 1,000. Titration and end-group assays showed the presence of approximately 2 terminal α-carboxyl groups and approximately 2 terminal α-amino-groups per 1,000 g. One α-amino terminal was recovered as DNP-alanine, but although the second N-terminal residue reacted with fluorodinitrobenzene, the resulting DNP label could not be released from the chromophoric group by acid hydrolysis. It was concluded that, in the native protein, at least three and possibly four peptide chains spring from two carboxyl groups and two amino groups in the chromophore, thus generating the cross-linked structure.

To obtain more information about the structure of the chromophoric group, a preliminary examination of the products of acid hydrolysis of the coloured peptide has now been made. After hydrolysis with 5·5 N hydrochloric acid at 100° two major ninhydrin-reacting components other than the known amino-acids were isolated. For preparative purposes, the two compounds were separated together as a single fraction by adsorption on alumina from 50 per cent v/v aqueous methanol solution followed by elution with water. The mixture was then further fractionated by use of a 30-cm column of sulphonated polystyrene resin (8 per cent divinyl-benzene) with 0·2 N citrate buffer of *p*H 4·25 at 50° C. Two sharp, well-separated peaks (compounds *A* and *M*) of almost equal ninhydrin colour value were obtained. Both compounds were hygroscopic, colourless solids, soluble in aqueous solvents, but not in dry methanol; attempts to induce them to crystallize were unsuccessful. The compounds both gave heavy ninhydrin spots of zero mobility on paper chromatograms using butanol/acetic acid/water (4 : 1 : 5). With ethyl acetate/water/pyridine (2 : 2 : 1) both substances moved as discrete spots with closely similar R_F values and both behaved as homogeneous substances on paper ionophoresis at 40 V/cm.

Compound *A* showed ultra-violet absorption at λ_{max}^{NaOH} 237 and 270 mμ and λ_{max}^{HCl} 235 and 269 mμ; in both solvents there were inflexions at 275 mμ. The infra-red spectrum showed the typical amino-acid pattern. The absorption maxima for ionized carboxyl showed at 1,600 cm^{-1} (asymmetrical) and 1,395 cm^{-1} (symmetrical) and the amino-acid I and II bands (deformation frequencies) at 1,630 and 1,530 cm^{-1}. An ionized amino-group (stretching frequency) appeared at 3,020 cm^{-1}. The compound after drying at 100° analysed for $C_{26}H_{44}N_5O_8$ (found: C, 56·5; H, 8·1; N, 12·8: formula requires C, 56·2; H, 8·1; N, 12·6).

The titration curves showed 7·2 basic groups per 1,000 g titrating between *p*H 7 and *p*H 11·5 (3·6 groups per 1,000 g titrated with midpoint at *p*H 8·80 and 3·6 groups with midpoint at *p*H 9·85). The titre from *p*H 5·0 to *p*H 1·4 was 5·8 groups, but the titration was incomplete at *p*H 1·4 and showed an anomalous deflexion between *p*H 1·4 and *p*H 1·2. The best fit to the titration curve was given by a minimum molecular weight of 278 with groups at pK_1 1·70; pK_2 2·40; pK_3 8·80; pK_4 9·85; the curve suggested the possibility of a further group titrating acid to *p*H 1·60. Since the minimum molecular weight from elementary analysis is 555 the compound contains four charged amino- or imino-groups and four charged carboxyl groups, with the suggestion of a weakly basic group titrating in the extreme acid range. The compound thus reacts as a tetracarboxylic–tetra-amino-acid. This formulation accounts for the eight oxygen atoms of the empirical formula and four of the five nitrogen atoms. The ultra-violet spectrum suggests that the remaining nitrogen atom may be part of a heterocyclic ring.

Compound *M* showed ultra-violet absorption at λ_{max}^{NaOH} 282 mμ (inflexion, 290 mμ) and λ_{max}^{HCl} 280 mμ (inflexions at 285 mμ and 217 mμ). The infra-red spectrum showed the same typical amino-acid pattern as compound *A* and was closely similar in other features. The substance, dried at 100°, analysed for $C_{26}H_{41}N_5O_8$ (found: C, 56·6; H, 7·5; N, 12·8: formula requires C, 56·6; H, 7·4; N, 12·7). The titration curve was almost identical with that of compound *A* in the alkaline region (pK_3 8·80, pK_4 9·85) but the amount titrating between *p*H 7·0 and *p*H 11·5 was somewhat greater (7·5 groups per 1,000 g). The acid titre was identical for both compounds (pK_1 1·70, pK_2 2·40). On the basis of the titration of the two groups in the alkaline region the minimum molecular weight for compound *M* was 267. The minimum molecular weight from elementary analysis was 551 and the compound must again be formulatd as a tetra-carboxylic–tetra-amino-acid.

Compounds *A* and *M* are thus closely similar in composition, but differ in degree of unsaturation. The molecular weights of the compounds are sufficient to account for the greater part of the estimated residue weight of the chromophoric group in the coloured cross-linked peptide isolated from elastin, and the compounds may be degradation products of a single chromophore or may be derived from two such chromophores of similar but not identical compositions.

We thank Miss J. M. Barrance for carrying out the combustion analysis, Dr. M. J. Fishwick for the infra-red spectra and Mr. J. R. Bendall for the titrations.

Changes in Liver D-Glucuronolactone Dehydrogenase Activity

D-GLUCURONOLACTONE dehydrogenase occurs in the non-particulate fraction of liver homogenates, and in the presence of nicotinamide adenine dinucleotide (NAD) converts D-glucuronolactone to D-glucaric acid[1]. The enzyme is probably responsible for the D-glucaric acid excreted in normal mammalian urine[2]; its activity is conveniently measured by the specific inhibitory effect of D-glucarate, after heating at acid *p*H, on β-glucuronidase.

The dehydrogenase activity in mouse liver was found to be negligible in infant animals, and increased to a maximum value in 8-weeks old animals (Table 1). Similar results have been obtained with rats, and values for human fœtal (3–4 month) liver were about 50 per cent those of adult specimens.

Table 1. CHANGES IN MOUSE-LIVER D-GLUCURONOLACTONE DEHYDROGENASE ACTIVITY WITH AGE AND PREGNANCY

Strain was Tyler's Original (Mill Hill colony). Results are expressed in μmole D-glucaric acid produced in 1 h from 5 mM-D-glucuronolactone and 2 5 mM NAD at 37° and *p*H 6·5 (ref. 1), and values given as mean ± *S.E.*

Age (weeks)	Sex and No. of animals	Enzyme activity (μmole D-glucaric acid) Per g liver	Per whole liver
2	Male (3)	0 14 ± 0 04	—
4	Male (5)	5·3 ± 0 11	—
8	Male (5)	24 6 ± 2·1	—
11	Male (3)	19 9 ± 8 0	—
11	Female (4)	17 5 ± 2·4	20 1 ± 3 0
11	Female (7) (18 days pregnant)	24 2 ± 1 0	41·5 ± 2·3

Table 2. CHANGES IN FEMALE MOUSE-LIVER D-GLUCURONOLACTONE DEHYDROGENASE ACTIVITY IN ANIMALS CARRYING TUMOURS

All animals (*SAS* strain) were of the same age before treatment; groups 1–4 were killed 16 days after treatment and groups 5–8 were killed 7 days after treatment. Results are expressed as in Table 1

Group and No. of animals	Tumour and route of administration	Enzyme activity (μmole D-glucaric acid/g liver)
1 (3)	None	14·0 ± 1·5
2 (6)	Ehrlich subcutaneous	8·2 ± 0·9
3 (5)	*T*2146 subcutaneous	10 3 ± 1·2
4 (3)	*S*37 subcutaneous	7·5 ± 1·6
5 (3)	None	18·2 ± 1·2
6 (4)	Ehrlich intraperitoneal	9·0 ± 1·0
7 (4)	*T*2146 intraperitoneal	5·4 ± 1·5
8 (3)	*S*37 intraperitoneal	5 0 ± 1 4

The increased excretion of D-glucaric acid during human pregnancy[2] was reflected by a rise in the liver dehydrogenase activity of pregnant mice, also shown in Table 1. This change was more marked when comparing total liver enzyme activity, due to the increased organ weight of the pregnant animals. A decrease in the enzyme activity of uninvolved liver tissue occurred in mice bearing experimental tumours produced by the subcutaneous or intraperitoneal injection of tumour-cell suspensions (Table 2); autopsy specimens of histologically tumour-free liver from human subjects with cancer have also shown considerably reduced dehydrogenase activity.

Speculation on the significance of these changes must await investigation of the possible physiological action of the D-glucarate produced, for example, as a potential inhibitor of endogenous β-glucuronide hydrolysis.

Enzymatic Cyclization of L-Glutamine and L-Glutaminyl Peptides

The following observations suggest that papaya latex contains an enzyme which catalyses the cyclization of L-glutamine and of L-glutaminyl peptides.

When commercial crude papain or dried papaya latex was added to a solution of L-glutamine and the *p*H adjusted to 7–12, free ammonia was formed at the expense of amide ammonia. At the optimal *p*H of 10, 1 mg of the soluble fraction of crude papain (Merck) caused the liberation of 0·057 μmole ammonia from 0·025 M L-glutamine solution per minute at 30° C. Paper chromatography showed that the glutamine was simultaneously converted to a compound which did not stain with ninhydrin, but which stained with starch-iodide following chlorination[1], and which had the same R_F in *n*-butanol/acetic acid/water (4 : 1 : 1) as pyrrolidone carboxylic acid.

These changes were not observed with D-glutamine, or with crude papain solution which had been heated at 90° C for 20 min. They were not substantially affected by dialysing the papain or by pretreating it with iodoacetate (0·01 M) or ethylenediamine-tetraacetic acid (0·01 M). Pure papain and chymopapain were inactive. Unlike the non-enzymatic cyclization of glutamine[2,3], the foregoing reaction was not accelerated by phosphate or bicarbonate.

Glutamine derivatives such as L-glutaminyl–L-leucine and L-glutaminyl–L-asparagine were de-amidated and converted to ninhydrin-negative compounds by crude papain considerably more rapidly and at a lower *p*H than L-glutamine.

Damodaran and Ananta-Narayanan[4] examined the formation of ammonia during enzymatic proteolysis and concluded, *inter alia*, that crude papain contains a de-amidase. The possibility that this de-amidase is identical with the foregoing enzyme is at present being investigated.

Iron Metabolism in Avian Erythroblastosis

Earlier work[1,2] has indicated a disturbance in iron metabolism in avian erythroblastosis, a virus disease of chickens in which there is an erythroblastic hyperplasia of the bone marrow with the entry of primitive red cells into the circulating blood. In normal birds injected intravenously with iron-59, the radioisotope disappears from the plasma and reappears in 24–48 h. In birds with erythroblastosis the activity reappears more quickly[1], autoradiographic investigations in blood smears suggesting that most of the activity is associated with the primitive cells[2].

Combined electrophoretic and autoradiographic studies, made on a limited scale, have shown that most of the radioactive iron in the cellular elements of leukæmic blood is not in the form of hæmoglobin. Similar *in vitro* studies were made. Blood samples from five normal and eight leukæmic birds were incubated with iron-59 and aliquots were removed at 6 and 24 h. The samples were separated into plasma and red cells, and hæmolysates were made of the latter. Both plasma and hæmolysates were subjected to electrophoresis and autoradiography. As incubation of the normal blood proceeded, radioactivity in the plasma β- and γ-globulin bands declined parallel with its appearance in the hæmoglobin bands. In two of the five normal blood hæmolysates, a small amount of activity was present in a component other than hæmoglobin. This component migrated with about half the speed of the slowest hæmoglobins, comparable with the speed of fowl 'ferritin'[3]. Autoradiographs of electropherograms prepared in the same way from the eight *in vitro* incubated leukæmic bloods showed marked radioactivity in a position corresponding to this slow band with only slight activity in the hæmoglobin region.

Two alternative explanations can be offered: either 'blocking' of iron occurs at an early stage in the synthesis of hæmoglobin, or diversion of iron occurs to sites other than hæmoglobin. In the former the intermediate would accumulate in the primitive cells, with elevation of non-hæm iron; in the latter such an increase would not occur. It was thought that determination of non-hæm iron in the liver and whole blood would help point to the correct alternative. Kennedy's thiocyanate method for total iron[4] was used with normal and affected livers; a micro-modification was used with whole blood[5]. Non-hæm iron was determined by these methods after its extraction by pyrophosphate[6]. All figures obtained are based on the average of duplicates. Adult birds (6 normal and 10 leukæmic) were used for the liver determinations and five-week-old chicks (17 normal and 32 leukæmic) for the blood determinations. The non-hæm iron was markedly elevated in the liver but not in the whole blood (Table 1). Blood smears stained for iron by Perl's method also failed to show evidence of free iron in the mature or primitive cells. The absence of a major elevation of non-hæm iron in the blood could point to a cycling of iron through the cells without it reaching hæmoglobin and, instead, reaching a non-hæm iron pool in the liver (and possibly the spleen[1]). The non-hæm iron in the liver is bound to a protein with some of the properties of a ferritin. The protein is heat resistant, contains non-hæm iron and is precipitable with 35 per cent ammonium sulphate and 4 per cent cadmium sulphate[7].

These observations raise many questions, which include the following: Is the non-hæm iron complex appearing in the *in vitro* cultivated blood 'ferritin'? Is the disturbance

Table 1. TOTAL AND NON-HÆM IRON IN THE LIVER AND BLOOD OF NORMAL BIRDS AND BIRDS WITH ERYTHROBLASTOSIS

	Normal	Erythroblastosis
Total iron		
Liver (mg/g tissue)	0·87 ± 0·07	2·98 ± 0·44
Blood (mg/100 ml.)	28·37 ± 0·66	23·44 ± 0·70
Non-hæm iron		
Liver (mg/g tissue)	0·58 ± 0·05	2·79 ± 0·49
Blood (mg/100 ml.)	1·85 ± 0·20	2·14 ± 0·20

in iron metabolism the result of virus-induced alterations in the red cells, or plasma, or both, or is it the indirect result of increased cell destruction ? Finally, is the disturbed iron metabolism responsible for the hæmatological changes which occur in erythroblastosis[8] ? Work on these problems is proceeding.

Enzymatic Investigations of Partially Purified Hog Kallikrein

KALLIKREIN, discovered by Frey in 1925 [1], was observed to be a hypotensive agent. Later work by many investigators has led to the present hypothesis that kallikrein is an enzyme, formed from a precursor kallikreininoken, which acts on protein substrates to liberate the biologically active polypeptides, substance *P*, kallidin II, and bradykinin. It is these substances which manifest the hypotensive activity[2,3]. Because trypsin possesses the same ability to release active polypeptides, it becomes important for future investigations to differentiate clearly the two enzymes, trypsin and kallikrein.

It has been noted in the literature that kallikrein has activity on synthetic substrates[4,5]. We have used these substrates to differentiate trypsin from kallikrein. The compound benzoyl arginine ethyl ester (BAEE) is a specific substrate for trypsin-like enzymes. Hydrolysis of BAEE yields benzoyl arginine and ethyl alcohol and can be measured directly by following the increase in optical density at 253 mμ on a Beckman *DU* spectrophotometer. This increase is directly proportional to the amount of enzyme present[6]. Utilizing 10^{-3} M BAEE in 0·05 M phosphate buffer *p*H 7·0 we have derived activity curves for kallikrein (Fig. 1).

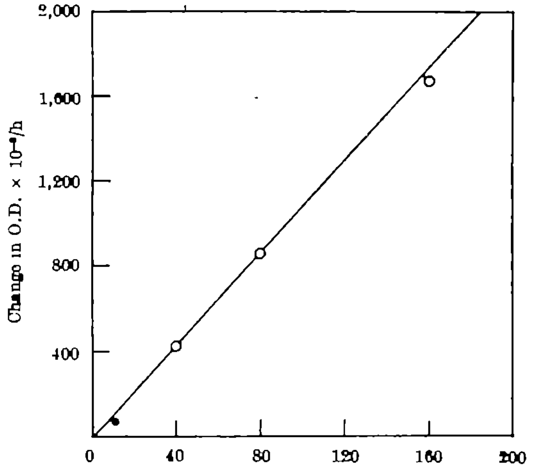

Fig. 1. Indicated amounts of enzyme incubated with 3·0 ml 10^{-3} M BAEE in total volume of 3·4 ml.

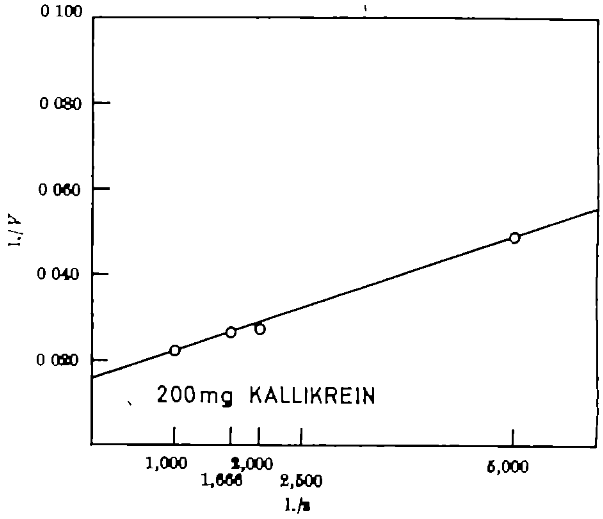

Fig. 2. Relationship of BAEE concentration to reaction velocity. $Km = 3·7 \times 10^{-4}$

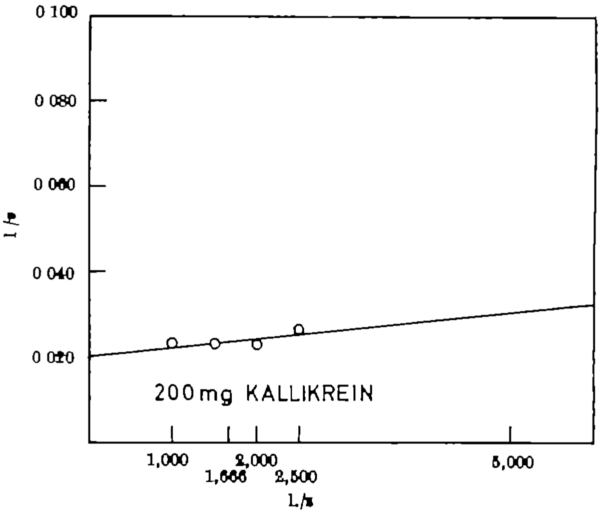

Fig. 3. Relationship of BAME concentration to reaction velocity $Km = 1·8 \times 10^{-4}$

By varying the substrate concentration, it is possible to deduce Michaelis constants for kallikrein. Using the equations of Lineweaver and Burke[7]: $\frac{1}{v} = \frac{Km}{V} + \frac{1}{V}$, we have found the *Km* of kallikrein on BAEE to be $3·7 \times 10^{-4}$ (Fig. 2).

We have also measured the *Km* of kallikrein for benzoyl arginine methyl ester and find it to be $1·8 \times 10^{-4}$ (BAME) (Fig. 3). Both *Km*'s differ greatly from the *Km* of trypsin, which is $8·0 \times 10^{-6}$ (ref. 8). The similarity of the two *Km*'s for kallikrein is to be expected since the stereochemistry of the two substrates BAEE and BAME is similar.

Addition of 10^{-2} M calcium chloride results in a 1·25 increase in activity of trypsin as reported by Neurath[9]. We have been able to show the increase in activity with respect to trypsin but 10^{-2} M Ca^{++} has no stimulatory effect on kallikrein.

The synthetic ester toluene sulphonyl arginine methyl ester (TAME) is active with trypsin and its activity can be measured by increase in optical density of 253 mμ. Kallikrein has no activity with TAME (Table 1). To rule out the contamination of kallikrein by chymotrypsin, the enzyme was assayed for chymotryptic activity with the synthetic substrate acetyl tyrosine ethyl ester (ATEE) by the method of Schwert and Takenaka[6]. No activity for chymotrypsin was detected.

Table 1. COMPARISON OF KALLIKREIN AND TRYPSIN ON TAME

Enzyme	Δ O.D. with BAEE × 10^{-3}/h	Δ O.D. with TAME × 10^{-3}/h
200 μg Kallikrein	2,700	0
20 μg Trypsin	10,000	2,600

Kallikrein was found to lyse fibrin clots by the method of Astrup and Mullertz and Lassen[10] and also to have caseinolytic activity. No plasminogen activating activity could be determined. Thus, kallikrein is unable to convert plasminogen to plasmin. (We would like to thank Dr. Edwin O. Salzman, who performed these assays.)

The enzyme loses its activity above 55° C. It shows the same pH optimal curve as reported by Webster[5].

Differences in the action of trypsin inhibitors on kallikrein and trypsin were also found. These differences will be the subject of another publication. This evidence strongly suggests that kallikrein is a distinct enzyme. Further evidence must await greater purification of kallikrein.

We thank Dr. G. Cronheim, Riker Laboratories, Northridge, California, who supplied the partially purified hog pancreatic kallikrein (1 Frey unit/88 μg).

This work was supported by the U.S. Public Health Service, grant No. A-5900.

A Water-soluble Lipid Complex obtained in the Macromolecular Phase by Gel-filtration of Human Bile

THE manner in which cholesterol remains soluble in the bile is of interest since it may be of importance for the formation of gall stones.

That cholesterol is present in the bile in some form of macromolecular complex has been suggested by some authors. Isaksson[1] isolated a complex from freeze-dried bile consisting of lecithin and bile acids which *in vitro* dissolved cholesterol. By electrophoresis of bile, Verschure *et al.*[2] and later Juniper[3] found a lipoprotein complex which also contained bile pigment.

The aim of the work recorded here was to separate a presumptive macromolecular complex in native human bile from other bile components. For this purpose, gel-filtration was used since it permits the separation of large molecular components such as proteins from other components of lower molecular weight.

The material was human gall-bladder bile. The gel used was 'Sephadex' (Pharmacia) type G–25 medium and G–75 medium (limits for complete exclusion are for G–25 in the molecular weight range of 3,500–4,500 and for G–75 in the range 40,000–50,000).

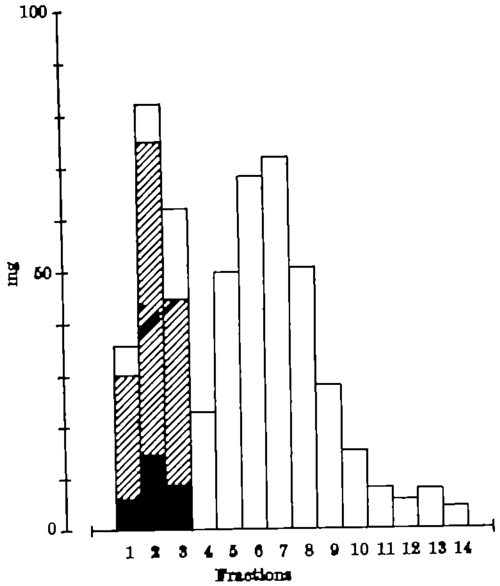

Fig. 1. Amount of solids, cholesterol and phospholipids in the 25-ml. fractions collected during gel-filtration of 3 ml. bile. Double hatching, cholesterol; single hatching, phospholipids; white, other components

An aliquot of 3 ml. of the bile sample was carefully pipetted on to the top of a 'Sephadex' column (diam. 2·5 cm, length 40 cm) and eluted with distilled water at a constant pressure of 50 cm of water. Fourteen fractions of 25 ml. were collected and freeze-dried. The solids in each fraction were extracted with diethyl ether or first with ether and then with chloroform. Analyses of the cholesterol in the lipid extracts of the fractions were performed according to the method of Theorell as modified by Cramér and Isaksson[4]. The amount of phospholipids was determined by analysis of the phosphorus content according to Fiske and Subbarow[5].

The fractions were grouped into two parts. Part I corresponded to the volume in which the large components of high molecular weight such as protein are to be found, and part II comprised the fractions where small components of low molecular weight are to be found.

The results show that the cholesterol and phospholipids were only found in part I (Fig. 1), and that this was the total amount of these two components in the sample may be seen in Table 1. Fractions 1–3 were green and slightly opalescent. The other fractions comprising part II were slightly green or yellow-brown and clear.

Table 1. CONTENT OF SOLIDS, CHOLESTEROL AND PHOSPHOLIPIDS IN HIGH AND LOW MOLECULAR FRACTIONS OBTAINED BY GEL-FILTRATIONS ('SEPHADEX' G–25) OF A 3-ML. SAMPLE OF HUMAN BILE COMPARED WITH A CONTROL SAMPLE FROM THE SAME SPECIMEN

	3 ml. bile separated by gel filtration Part I	Part II	3 ml. freeze-dried bile
Solids (mg)	183	332	475
Cholesterol (mg)	28·5	0	30·0
Phospholipids (mg)	119·8	0	124 0

Bile from another patient was eluated on two different gels (G–25 and G–75) and only part I of each filtration was analysed (Fig. 2 and Table 2). Essentially the total amounts of cholesterol and phospholipids were recovered in part I independent of the type of the gel used. The solutions were green and slightly opalescent.

Table 2. CONTENT OF SOLIDS, CHOLESTEROL AND PHOSPHOLIPIDS IN THE HIGH MOLECULAR FRACTIONS AFTER GEL-FILTRATION ('SEPHADEX' G–25 AND G–75) OF BILE SAMPLES COMPARED WITH THE TOTAL CONTENT IN A CONTROL FROM THE SAME SPECIMEN

	3 ml. bile Part I G–25	3 ml. bile Part I G–75	3 ml. bile Total
Solids (mg)	28·5	26·1	95
Cholesterol (mg)	3·7	3·7	3·6
Phospholipids (mg)	16·2	16·8	19·6

Thus by gel-filtration of native bile all the cholesterol and phospholipids were eluated in an opalescent green water solution in the macromolecular phase, in which proteins and other substances of molecular weights of

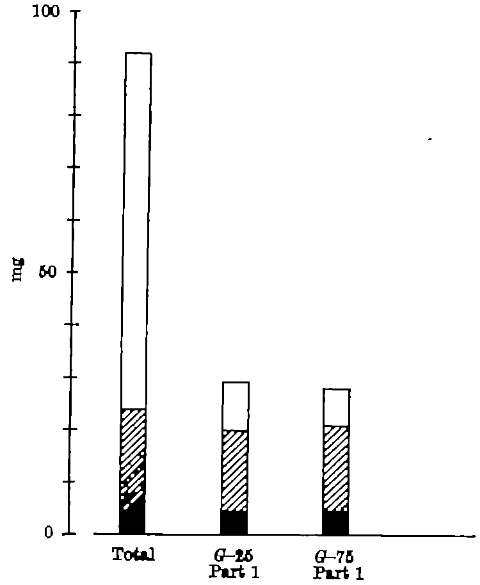

Fig. 2. Amount of solids, cholesterol and phospholipids in the 3 ml. bile compared with the amounts found in the high molecular fractions of the same quantities of bile after gel filtration on 'Sephadex' *G*–25 and *G*–75. Double hatching, cholesterol; single hatching, phospholipids, white, other components

> 40,000–50,000 are presumed to be found. The bile lipids, cholesterol and phospholipids comprise more than 2/3 of the solids, in this phase. The rest probably consists of the bile pigment, biliverdin and protein.

The bile lipids, cholesterol and phospholipids, may be present in some form of macromolecular water-soluble complex which can be separated from native bile with the large components such as proteins. Some of the bile pigment (biliverdin) accompanies these substances.

Accumulation of Hæmatins by Polychætes

MANY polychæte annelids appear to darken with age; the lugworm *Arenicola marina* does so, and the terebellid *Amphitrite johnstoni* is also brown when old. In terebellids the heart-body becomes bulkier and in lugworms dark tissue around the intestinal vessels increases with age. This darkening is partly due to an accumulation of hæmatin; in *Amphitrite johnstoni* the dark colour is wholly due to hæmatin, the pigment accumulating in the cœlomic cells as well as in the heart-body. In *Arenicola marina* the hæmatin in the skin and that in the tissue surrounding the intestinal vessels both show pyridine hæmochromogen bands at 547·5 and 517 mμ. In *Amphitrite johnstoni* the hæmatin in the cœlomic cells to which, owing to the transparency of the body wall, the hue of the worm is due shows pyridine hæmochromogen bands at 554 and 520 mμ; that from the heart-body at 547 and 516 mμ, reminiscent of meso- rather than proto-porphyrin and similar to the malarial pigment. The hæmoglobin in the blood of both worms, and the hæmoglobin in the cœlomic cells of *Amphitrite johnstoni* show pyridine hæmochromogen bands at 557 and 525 mμ characteristic of hæms with protoporphyrin nuclei.

The accumulation of hæmatin with age in tissues which are known to be also hæmatopoietic[1] suggests that hæmatin may be a normal product of hæmoglobin breakdown in these worms. It may be that the reason why bilins of chlorocruorin have not been identified is that normal breakdown of chlorocruorin also leads to equivalent hæmatins. The accumulation of bilins in some other polychætes[2–4] suggests that there may be some variety in the ways in which hæmoglobin is catabolized in these worms, but following the work of hEocha *et al.*[5] it is not clear whether these are always derived from the worms' own hæms or from algal pigments in the food.

An investigation of these problems is in progress.

ANATOMY

Effect of Total Thyroidectomy in the Rabbit Fœtus on Fœtal Cholesterol Metabolism

IN earlier communications[1,2] it was shown that the fœtal thyroid gland influenced the cholesterol metabolism of the rabbit fœtus. Total thyroidectomy in the 22–23 day fœtus was found to result in a highly significant increase in blood cholesterol and the results are shown in Table 1.

Table 1. SERUM CHOLESTEROL IN THYROIDECTOMIZED AND CONTROL RABBIT FŒTUSES

Fœtuses	Age at investigation	No.	Mean serum cholesterol (mg/100 ml. ± *S.E.*)
Thyroidectomized (at 22–23 days)	29–30 days	7	129* ± 7·7
Litter-mate controls	29–30 days	12	86* ± 3·5

* These differences are significant, $P < 0.001$.

The method used for fœtal thyroidectomy was similar to that described by Jost[3] and involves the removal of the lower half of the larynx and the upper rings of the trachea together with the thyroid gland. It was noted that the fœtuses which had undergone this operation were unable to swallow during intra-uterine life, the stomach of each operated fœtus containing a negligible amount of fluid whereas the control fœtuses all had full stomachs, presumably from intra-uterine swallowing of amniotic fluid. This raises the possibility that the mechanical interference to the neck of the fœtus, by preventing swallowing, may have been responsible for raising the cholesterol-level in the fœtal blood.

In order to investigate this point further a new technique has been developed for removing the thyroid of the rabbit fœtus. The strap muscles overlying the thyroid are divided, exposing the gland, which is then divided into two parts by a verticle incision through the isthmus. Each lobe is dissected off the trachea and larynx under a dissecting microscope, the laryngeal nerves being left intact. The skin incision is closed with 3–4 fine sutures of Barraquer silk on a 4-mm corneal needle. When examined 6 days later just before term, these fœtuses had well-healed operation wounds, the trachea and œsophagus were free, but the stomach was filled with fluid as in the litter-mate control fœtuses. This new technique did not interfere in any way with fœtal swallowing.

Using this technique, ten fœtuses were subjected to thyroidectomy on the 23rd day of intra-uterine life, and then allowed to continue developing within the uterine cavity until just before term. The fœtuses were recovered by Cæsarean section on the 29th day of pregnancy after a further six days of development.

Blood was taken from these ten fœtuses and also from 25 litter mates for controls, and the serum cholesterol was estimated by the method of Abell *et al.*[4]. The results (Table 2) show a highly significant increase in serum cholesterol following fœtal thyroidectomy.

Table 2. SERUM CHOLESTEROL IN RABBIT FŒTUSES SUBJECTED TO TOTAL THYROIDECTOMY WITH PRESERVATION OF THE LARYNX AND TRACHEA

Fœtuses	Age at investigation	No.	Mean serum cholestero (mg/100 ml. ± *S.E.*)
Thyroidectomized (at 23 days)	29 days	10	118·5* ± 11 7
Litter-mate controls	29 days	25	71·12* ± 5·9

* These differences are significant, $P < 0{\cdot}001$.

This experiment therefore confirms that the fœtal thyroid of the rabbit is essential for the normal regulation of cholesterol in the fœtal blood. Further, maternal thyroid secretions are unable to compensate for the loss of the fœtal thyroid, although maternal hormones have been shown to cross the placenta in increasing quantities towards the end of pregnancy[5].

These results further confirm that the effects reported in the earlier communication[1] were due to the removal of the thyroid and not the interference with the swallowing mechanism of the fœtus resulting from the removal of the larynx.

PHYSIOLOGY

A Model System for Transcellular Active Transport

Oxender and Christensen[1] have proposed that the achievement of transcellular transport of amino-acids and sugars against concentration differences is a consequence of intracellular accumulation. Intestinal mucosal cells will accumulate certain sugars during absorption *in vitro*. McDougal, Little and Crane[2] have shown that, during the absorption of D-galactose by hamster intestine, the sugar concentration is greatest in the epithelial layer. Similar conclusions were also drawn for galactose and 3-O-methyl-glucose by Kinter and Wilson[3,4] from autoradiographic studies of hamster intestine. On the basis of their findings that the cells in the crypts of Lieberkühn also exhibit an intracellular accumulation of sugar, Kinter and Wilson suggest that, in the intestine, an intracellularly directed sugar pump "is present along the entire cell membrane, the net movement from lumen to blood being due to the far greater surface area because of the microvilli at the luminal border of the cell"[4].

The properties of a simple model system based on the hypothesis of Oxender and Christensen will now be described.

Consider an absorbing cell operating on material here called substrate. The cell is an element of a tissue composed of a single sheet of identical cells which separates two fluid compartments of infinite capacity (sides 1 and 2), each compartment containing substrate (sugar, amino-acid) at the same constant concentration a. It is supposed that the membranes composing the faces bordering either side of the cell possess both the following independent properties: (1) A substrate pump operating to move substrate at a rate p moles/sec from the external compartment into the interior of the cell. For simplicity the rate of pumping is considered to be constant and independent of both the internal (x) and external (a) substrate concentrations. (2) A diffusion leak of magnitude $K(x-a)$ moles/sec. Let the values for face 1 be p_1 and K_1 and for face 2, p_2 and K_2. It is assumed that substrate is conserved in the system, that is, that it is neither synthesized nor utilized by the cells.

For a unit volume of cell, with the internal concentration $x=0$ at zero time, the internal concentration of substrate after time, t, is given by:

$$x=[a+(p_1+p_2)/(K_1+K_2)]\,[1-\exp-(K_1+K_2)t] \qquad (1)$$

the uptake from side 1, across face 1:

$$A_1 = p_1 + K_1 a \exp - (K_1 + K_2)t - \frac{K_1}{K_1 + K_2}(p_1 + p_2)\,[1-\exp - (K_1 + K_2)t] \qquad (2)$$

and the output from the cell across face 2:

$$A_2 = \frac{K_2}{K_1 + K_2}(p_1 + p_2)\,[1 - \exp - (K_1 + K_2)t] - K_2 a \exp - (K_1 + K_2)t - p_2 \qquad (3)$$

In steady-state conditions, that is, when $(K_1+K_2)t$ has values large enough to reduce the exponential terms to insignificant levels, the limiting values are:

$$x_s \rightarrow a+(p_1+p_2)/(K_1+K_2) \qquad (4)$$

and

$$A_s=A_1=A_2\rightarrow(p_1K_2-K_1p_2)/(K_1+K_2) \qquad (5)$$

Under steady-state conditions provided $p_1/p_2 > K_1/K_2$, a transcellular transport of substrate will occur from compartment 1, across the cell, into compartment 2. It then follows that the rate of inward pumping into the cell may be greater at side 2 than side 1, yet, provided that $p_1/p_2 > K_1/K_2$, transcellular transport will still occur into compartment 2. If K_1 is zero, that is, there is no substrate leak across face 1, then $A_s = p_1$ and is independent of p_2 and K_2. If p_1 is zero, for finite positive values of p_2 the sign of A_s is negative, that is, the direction of the transport will be into side 1 from side 2. Hence in the model system, the ability to be pumped into the cell from side 1 by the process p_1 is a necessary but not a sufficient condition for substrate to be subjected to transcellular transport from side 1 to side 2. In general, for given positive values of p_1 and p_2, the absorption rate, A_s, in the system described is independent of the external concentration a and is determined by the value K_2/K_1, while the internal concentration, x, is determined by K_1+K_2 as well as by the external concentration, a.

The application of model systems of the sort described to active transport phenomena in tissues raises questions which appear to be capable of being resolved experimentally. It is also clear that any one particular property of even a simple transcellular transport system is not necessarily a property of the pumping mechanism on which the activity of the system is based. For example, in the absence of other evidence, the finding that pyridoxal or pyridoxal phosphate stimulates net amino-acid transfer across layers of tumour cells arranged as a membrane[1] may be explained as the result of effects of these substances either on an exit process or on an entrance pump for amino-acids or by a combination of both. The fact that 'active' sugar transport across the mucosal layers of the small intestine requires the presence of oxygen may not necessarily mean that aerobic conditions are essential for the activity of a sugar pump localized in the cell membranes; the effects are equally explicable if anoxia increases the relative leakiness of the mucosal faces of the absorbing cells ($K_1/K_2 \succ p_1/p_2$). In a similar fashion, differences in the relative leakiness of the faces of the two poles of mucosal cells from different regions of rat intestine may underly the differences in the capacity of these regions to absorb either glucose[5,6] or galactose[7]. Now a substrate may possess physical and chemical properties such that it can be operated on by the pumping process p, but these properties need not be the same as those which determine the magnitudes of K_1 and K_2. For example, in a given system, the former might depend on a particular stereochemical configuration of a substrate, while the K-values might depend on the molecular weight. D-xylose has not been shown to be actively transported against a concentration gradient in small intestine, but there is recent evidence suggesting an interaction between the pentose and glucose during absorption[8]. Xylose may share an inwardly directed sugar pump with glucose, but intracellular pumping, even at high rates, does not necessarily mean that transcellular active transport will occur.

In other similar model systems, but in which the processes underlying the substrate leak across the cell faces are more elaborate than those of simple diffusion (for example, facilitated diffusion), competition between substrate molecules for exit from the cell could have important effects. For example, the overall specificity of the whole system for transcellular transport of a particular class of substrates, including such effects as those of one substrate on another, will be the resultant of the specificity of the intracellularly directed pump for substrate and the specificity of the leak.

Stimulation of Insulin Secretion *In vitro* by Adenosine Triphosphate

WE have already shown that the metabolites (glucose, citrate, β-hydroxybutyrate), the final function of which is the production of energy in the $\sim P$ form[1,2], give place to release of insulin *in vitro* when they are added to the incubation buffer surrounding slices of pancreas. For this reason, we considered it interesting to determine if ATP when added to the incubation buffer produces any effect on the release of insulin, although what is generally accepted is that the metabolic processes in which this nucleotide takes part are intracellular.

A piece of rabbit pancreas weighing 200 mg was incubated for 3 min at 37° C in Krebs–Henseleit buffer containing ATP 1×10^{-3} M and another piece of the same weight (± 5 mg) was incubated in the same buffer but containing hydrolysed ATP (1×10^{-3} M–N/10 hydrochloric acid for 15 min at 100° C) as control (final pH 7). The insulin of the buffer was extracted by the method of Grodsky and Tarver[3] and evaluated by the technique using adipose tissue of the rat epididymis. The results are expressed in uptake of glucose and the statistical study was performed using the paired observations method[4].

Table 1. EVALUATION OF THE INSULIN (GLUCOSE UPTAKE) EXTRACTED FROM THE INCUBATION BUFFER (CONTAINING ATP OR HYDROLYSED ATP) SURROUNDING PIECES OF RABBIT PANCREAS

Metabolites		Mean glucose uptake mg/100 of tissue/4 h	
ATP (1×10^{-3} M)	(20)	1·082	± 0·066* P=0 01
ATP hydrolysed (1×10^{-3} M)	(20)	0·781	

**S.E.* The values in parentheses represent the number of experiments.

As can be seen from Table 1 the insulin extracted from the buffer of incubation containing adenosine triphosphate is higher than that obtained from the control. The difference is highly significant. We think that this fact supports our hypothesis about the role of the ATP in release of insulin.

We thank Dr. S. Ochoa for his advice. This work was supported by a grant from J. March Foundation.

Increased Survival-time in Dystrophic Mice treated with Methylandrostenediol Dienanthoylacetate

ANABOLIC steroids have been noted to increase survival time in dystrophic mice, *Jax*/129 (*dydy*), but the disease syndrome was not otherwise altered. Testosterone propionate did not possess this ability[1,2]. It was of interest to evaluate an anabolic steroid, 17-α-methylandrostene-5-diol-3β-17β-dienanthoylacetate (MADD), which has a prolonged period of activity.

Mice with hereditary muscular dystrophy (*dydy*) were obtained by mating *Jax*/129 *mice* (*Dydy*) from the Jackson Memorial Laboratory, Bar Harbor, Maine. The quarters were controlled to room temperature and Purina laboratory chow and water were available *ad libitum* in containers accessible to the dystrophic mice. Mice were weaned at 3–4 weeks with no special transitional diet, and experimental groups formed by dividing litters. A portion of the dystrophic mice were treated with 5 mg MADD in sesame oil per mouse in a single intramuscular dose per week, the dose being equivalent to the methylandrostenediol. Body-weights and mortalities were recorded to the nearest week, and post-mortem examinations were made on mortalities.

Survival time was increased approximately two-fold in the MADD-treated dystrophic mice as compared with untreated controls (Table 1), with no difference apparent between the sexes. Growth was approximately the same in the treated and untreated dystrophic mice with females

Table 1. RESULTS OF MICE TREATED WITH MADD

Group	No. of mice	Median survival-time and range (weeks)	Av. weight at 3 weeks (g)	Av. weight at 13–27 weeks (g)
Normal males	94	not detn.	10	32
Normal females	79	not detn.	9	26
Dystrophic males	13	5 (4–7)	7	dead
Dystrophic females	12	6 (4–9)	6	dead
Dystrophic males receiving MADD	22	13 (7–23)	7	21
Dystrophic females receiving MADD	25	18 (4–27)	7	19

generally weighing less than males. Histological examinations revealed degeneration in the skeletal muscle of all the dystrophic mice, and the treatment with MADD did not appear to alter the disease syndrome except to increase survival-time.

The survival-time of the untreated dystrophic mice was less than reported by some workers[1,2], possibly because a special diet was not employed during the weaning period. The survival data of this experiment approximated that of other workers employing conditions similar to those here[4,5]. The difficulties discussed by Miller *et al.*[6] in evaluating survival data with dystrophic mice are to be considered and necessitated the use of sufficient mice to allow for litter differences. Larger litters generally have dystrophic mice with small body-weights and poor survival.

It may be concluded that the treatment of mice with hereditary muscular dystrophy by an anabolic steroid, methylandrostenediol dienanthoylacetate, lengthened survival time but did not otherwise alter the disease syndrome.

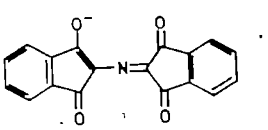
HISTOCHEMISTRY

Use of the Ninhydrin Reaction for Quantitative Estimation of Amino Groups in Insoluble Specimens

It is well known that the development of a purple colour (Ruhemann's purple) on reaction of ninhydrin with primary amino (NH_2) groups of proteins occurs even when the protein is not in solution. Thus, Pearse[1] describes attempts to use the ninhydrin reaction for histochemical staining of protein, which failed due to the ease of diffusion of the coloured product. In fact, the soluble purple compound, to which formula (I) is usually assigned, is not in any way attached to the protein; it results from deamination of the protein (left otherwise unchanged), the abstracted nitrogen being incorporated in (I)[2]. Under suitable conditions, the coloured product is released completely from the solid into the solution, and the quantitative ninhydrin estimation, usually carried out on dissolved amino-acids and proteins, then becomes equally applicable to insoluble material. All primary NH_2 groups react, ε-NH_2 groups (lysine residues) giving, for reasons which are not certain, 65–70 per cent of the colour yield of α-NH_2 groups, in almost all cases[3]. Where the former far outnumber the latter, as in tissue preparations and very many proteins, comparison with a standard gives the actual or relative amino content with fair accuracy. This appears to be the simplest method at present available for obtaining such information.



(I)

This technique for analysing insoluble and denatured proteins, and protein-containing material, is of particular value where it is desired to know the amino content of biological specimens before and after treatment with various cytochemical reagents. For this purpose, the test material is fixed, and subjected to reactions under cytochemical conditions, small weighed samples being analysed at each stage. (An alternative approach, not as yet pursued, would be to use serial microtome sections, comparing similar sections after different treatments. Weighing is thereby avoided, and since large numbers of sections will normally be required in each reaction tube to give a measurable colour, errors due to inherent differences between sections are minimized.)

To check the validity of the method, it was thought advisable to apply it to an insoluble protein of precisely known constitution. Lysozyme was therefore denatured by maintaining the dissolved protein at *p*H 9–10 and 37° C for several days, and then precipitating with ethanol, and its ninhydrin colour yield was compared with that of an amino-acid standard, under identical reaction conditions. 1 mole of lysozyme was found to be equivalent to 4·5 moles of leucine, in close agreement with the figure of 4·35 equivalents obtained by Slobodian, Mechanic and Levy[3] for the native protein (Tallan and Stein[4] earlier obtained the figure of 4·9). Assuming a contribution of 1·1 leucine equivalents from the *N*-terminal lysine residue, as is usual[3,5], colour due to the other five ε-NH_2 groups is, in the present case, 3·4 equivalents. This corresponds to an average yield from each of these ε-NH_2 groups of 68 per cent of the colour from an α-NH_2 group—that is, within the range 65–70 per cent normally expected.

On theoretical grounds, two factors could limit the accuracy of analysis of insoluble material, relative to that of the usual reaction in solution, namely, possible inaccessibility of some NH_2 groups to ninhydrin, and possible occlusion of some Ruhemann's purple by the solid. In practice, the second source of error is avoided, and the first minimized, so far as possible, by ensuring that each solid particle is very small in at least one of its dimensions, by limiting the quantity of material in each reaction tube, and by providing adequate agitation of the suspension while the colour is developing. Experience has shown that populations of single cells, such as sperm and amœbæ, may be used directly, provided that any clumps of the dried fixed material are broken up before analysing; mammalian tissues are normally finely powdered after fixation. It is advisable to restrict analysis to samples smaller than 5 mg, since variable results have sometimes been obtained with larger quantities. When reaction conditions, in a given case, have been satisfactory: (1) optical density values are reproducible, and increase more or less linearly with sample size; (2) no coloration occurs when the ninhydrin-reacted solid is washed with 50 per cent ethanol, or further reacted with ninhydrin; (3) colour yield does not increase when the material is more finely ground; (4) the colour of the ninhydrin-reacted specimen is not usually appreciably darker than before reaction (but is occasionally so). Where there has been any chemical treatment before analysis, it must be ensured that any products left bound or deposited in the solid do not interfere with the ninhydrin estimation.

The experimental procedure is essentially an extension of that of Moore and Stein[5]. Dried samples (1–4 mg) are accurately weighed into 15 ml. centrifuge tubes, and 1 ml. of buffered ninhydrin-hydrindantin reagent is added to each. The tubes are covered with aluminium foil, and shaken at about 200–500 oscillations per minute in a boiling water bath for 15 min, using a flask shaker. The tubes are then removed to a cold water bath, where 5 ml. of 50 per cent ethanol are added, and are shaken to mix before spinning down the solid. (Due to the shaking, the hydrindantin disappears at the time of boiling.) For tissue specimens, further six-fold dilution of a portion of the supernatant will normally bring the colour into the range where its optical density can be measured on a colorimeter or spectrophotometer. A different final dilution ratio may be required for some other materials, such as denatured proteins exceptionally rich or poor in lysine. A blank is included with every group of analyses.

The method as described is at present being utilized in a programme of development of specific electron stains for protein[6], as a guide to the extent and specificity of reactions, and has been applied to rat liver, ram sperm and *Amoeba proteus*, with ethanol, osmium tetroxide and formalin as fixatives. While results of these investigations lie outside the scope of this communication, attention may be directed here to the need for caution in interpreting ninhydrin data, in certain instances. In particular, there is some indication that, after osmium fixation, many more NH_2 groups may be available for reaction than are revealed by ninhydrin. This apparent 'blocking' has not yet been explained, but the observation underlines the need to apply a multiplicity of analytical techniques when attempting to interpret cytochemical reactions.

I thank Dr. E. A. Barnard for advice. This work was carried out while in receipt of a grant from the Department of Scientific and Industrial Research.

The Periodic Acid – Schiff Reaction

THE periodic acid–Schiff (PAS) reaction—the term was introduced by McManus[1,2]—is one of the most widely used histochemical methods. In a recent review of "Periodate Oxidation Techniques" McManus[2] states that the first publication, describing the demonstration of mucin and some other structures by the Schiff reagent after treatment with periodic acid, appeared in *Nature* in 1946[3]. In 1948 Hotchkiss[4] published his description of the PAS reaction, which had been applied already in 1947 by Gersh[5] and by Catchpole[6]. Also in 1947 Marchese[7] used the PAS reaction for the demonstration of glycogen, but independently Lillie[8] used acidified periodate for the same purpose. Since other histochemical texts[9–11] give essentially the same version of the development of our knowledge of the PAS reaction, we should like to direct attention to the work of A. L. Shabadash, whose publications on the PAS reaction apparently are not widely known outside the U.S.S.R.

At a meeting of the Institute for Biology and Biochemistry of the Academy of the Medical Sciences of the U.S.S.R., held on February 14, 1946, Shabadash presented a paper on "A Rational Method for the Histochemical Determination of Glycogen, and its Theoretical Basis". This paper was published in 1947 (ref. 12). After surveying critically the methods in use for the fixation and demonstration of glycogen Shabadash discusses Bauer's method[13], and goes on to say that he experimented with several other oxidants, among them potassium permanganate, but that he was unable to produce the reactive aldehyde groups necessary for the interaction with leukofuchsin. ". . . After a whole row of experiments and investigations I settled on periodic acid which was proposed by Malaprade (1927) and used by Jackson and Hudson (1937) for the study of the structure of starches. . . . I investigated the action of dilute (0·01 mol.) solutions of periodic acid on glycogen *in vitro* and in control preparations (sections of liver) with subsequent treatment with leukofuchsin. The results proved the correctness of the theoretical assumptions. The brightness and intensity of the colour reaction was superior to that of any of the methods published in the literature or known to me; it differed from them not only in the degree of sensitivity, but also in its chemical basis . . ." Shabadash realized that this method was applicable not only to the identification of glycogen, but also of polysaccharides in general. He used both periodic acid and sodium or potassium periodate in water in dilutions which, depending on the amount of glycogen present in the tissues, varied from 0·01 mol. (0·23 gm. per cent) periodic acid to 0·002 mol. periodate. The time of exposure varied from 15 to 25 min. No reducing rinse, only distilled water, was used as a wash. After 20–25 min in leukofuchsin the sections were rinsed in a sulphite wash.

Several points are of interest in this publication.

(1) Shabadash discusses the nature of the PAS reaction, its specificity, the necessity of enzymatic digestion for control purposes, and the possibility of substances other than complex carbohydrates responding to this treatment, at length, so that his paper is unquestionably the most detailed account of the PAS reaction published at that time.

(2) Although Shabadash extensively quotes the work of earlier writers who have investigated the histochemical demonstration of glycogen or other carbohydrates, he does not mention the first publication by McManus[3] of whose work he, presumably, did not know.

(3) Shabadash's paper appears to be the result of a prolonged, systematic search for a specific histochemical method for the detection of glycogen.

(4) In the paper summarized here Shabadash states that the colour obtained is stable and permits the preservation of histological sections under ordinary conditions for years. He then adds: "I have preparations which have preserved their original brightness for seven years". He makes a similar claim in another publication, an extensive monograph on the histochemistry of the normal central nervous system, which appeared in 1949 (ref. 14). In a footnote on p. 104 he states "My preparations have retained their brightness over a period of five to seven years". According to these claims, then, Shabadash had used the PAS reaction as a histochemical tool some time between 1939 to 1944. It should be pointed out that the work of Hotchkiss, started in 1945, remained unpublished for three years, so that Shabadash cannot have known of it.

IMMUNOLOGY

Loss of Immunological Reactivity of an Alpha-2 Globulin after Prolonged Freezing of Serum

Most investigators who preserve sera for future analysis take it for granted that the serum proteins are stable at temperatures around −20° C. Some evidence supports this assumption: the titres of certain antibodies or of rheumatoid factor, for example, remain unaltered after even several years in a deep freeze. This communication shows that most human sera, from both healthy and sick people, contain an α-2 globulin which loses its antigenic (precipitin) characteristics after prolonged storage at −20° C.

An antihuman serum was made by injecting a rabbit intravenously with 1 ml. of pooled human serum three times weekly for eighteen months. This pool was made by combining equal amounts of serum from 200 patients in a State hospital. Immunoelectrophoresis using the antihuman serum and several human sera showed antibodies to various proteins including about 10 α-globulins. The antihuman serum was absorbed with another serum pool made by combining equal amounts of serum from 20 blood donors. 1 ml. of the antiserum was mixed with 25 μl. of the blood-donors' pooled serum, left at room temperature for 30 min and then centrifuged at 3,500 r.p.m. for 10 min. Using a small-scale double-diffusion-in-agar technique[1], 0·5 μl. amounts of each reactant were placed in wells the centres of which were 8 mm apart and the edges 4 mm apart. The preparations were left in a moist chamber at room temperature for 48 h.

When a recently drawn human serum and the absorbed antiserum were used as reactants, two precipitin lines could usually be seen. The first (line 1) was a dense line, occasionally closely split, present about 1 mm from the edge of the well containing the human serum. The second (line 2) was a hazy, faint line present about 1 mm from the edge of the well containing the absorbed antiserum. There was no reaction between the absorbed antiserum and saline, nor between human serum and rabbit serum taken before immunization had been started.

When the human serum had been kept for a long time in a deep freeze at −20° C, line 2 tended to disappear, an observation made in more than 1,100 sera taken from both healthy and ill persons. Table 1 shows the findings in 763 different sera for which the dates of drawing were precisely known. Line 2 was seen in all freshly drawn sera; in about 30 per cent of sera stored for 9 months; and in only 5 per cent of sera stored for 30 months. Among 36 freshly drawn sera, line 2 was present in all; on retesting 14 weeks later, 5 of them had entirely lost line 2. The disappearance of line 2 depended more on the length of time the serum had remained frozen than on either mere freezing or the number of times the serum had been frozen and thawed, because there was no diminution in the intensity of line 2 in 20 freshly drawn sera which had been 20 times rapidly brought to the temperature of dry ice and then thawed. Nor did heating the serum at 56° C for 30 min cause line 2 to change intensity.

Both line 1 and line 2 were shown by immunoelectrophoresis on cellulose acetate to be α-2 globulins. Line 1 was immunologically identical with that produced by the S_f 0–400 lipoproteins (isolated in an analytical ultracentrifuge, and provided by the Institute of Medical Physics). Line 2 has not been identified. Use of commercially available serum fractions and antisera showed it to be neither cœruloplasmin nor α-2 macroglobulin. The absorbed antiserum did not react with fibrinogen, and addition of neither heparin nor thrombin to fresh sera abolished line 2—so that line 2 is probably neither a cryofibrinogen nor the heparin-precipitable protein described by Thomas, Smith and Von Korff[2]. Siderophyllin, Cohn's fractions II, III and IV 5 + 6, and an isolated cryoglobulin did not react with the absorbed antiserum.

Table 1. Presence or Absence of Line 2 in 763 Different Sera for which the Dates of Drawing were known

Age of serum	Total No.	Line 2 present	Line 2 absent
3 days	79	79 (100%)	0
2 weeks	80	80 (100%)	0
1–3 months	91	89 (98%)	2 (2%)
3–6 months	88	71 (81%)	17 (19%)
6–9 months	86	59 (69%)	27 (31%)
9–12 months	68	18 (26%)	50 (74%)
12–15 months	40	13 (32%)	27 (68%)
30–36 months	231	12 (5%)	219 (95%)

These investigations show that most human sera contain an α-2 globulin which loses its immunological reactivity after a long period in the deep freeze. Although stored sera are used all over the world for numerous investigations, systematic investigations have not been made of the effects of lengthy storage of the serum on the various proteins; nor has a comparison been made of the various methods of preservation to determine the least deleterious. The results of such inquiries would be valuable

Development of the Fœtus in Female Rats Injected with Homologous Heart Tissue

Recent observation of the occurrence in human beings of auto-antibodies specific to heart tissue has given support to the hypothesis of an auto-immune ætiology in rheumatic fever, following myocardial infarction and postcardiotomy state[1,2]. In the rabbit, heart-specific antibodies have been produced readily against heterologous heart tissue and much less readily against homologous heart tissue[3-5]. While there is good evidence from clinical and experimental sources of the existence of antiheart antibodies whether from autologous, homologous or heterologous stimuli, there is considerable confusion as to the part they play in cytotoxic action on the heart. If antiheart antibodies are cytotoxic then they could readily influence developing embryonic heart tissue to produce either arrested growth with persistent anomalies or death. The possibility that such an immune (auto-immune) mechanism may play a part in the development of congenital heart disease seemed worthy of investigation.

Mature Sprague–Dawley female rats were immunized with homologous rat heart tissue one week before mating, approximately at the time of mating, and one week following mating. The number of new-born, their weight, and the gross and histological changes in the heart of the new-born were evaluated. Antigen was prepared from adult rat hearts of Sprague–Dawley rats removed shortly after death. The hearts were trimmed of connective tissue, minced with scissors and rinsed with cold saline to remove visible traces of blood. Extracts were made by homogenation with 4 times the tissue volume of saline carried out for 3 days at 4° C. The antigen was mixed with equal parts of complete Freund's adjuvant and emulsified. Female rats were divided into 3 experimental groups and 3 corresponding controls. Group I consisted of 5 female rats, 4 injected 7 days and 1 injected 12 days before mating (1 ml. of the antigen emulsion, 0·5 ml. subcutaneously and 0·5 ml. intraperitoneally). Group II consisted of 4 females immunized the morning following mating, and Group III consisted of 3 females immunized 7 days following mating. Control animals were mated at the same time as the experimental counterpart but were

Controls mated on same day as experimental counterpart. † Parentheses indicate re-immunized and re-mated

not immunized. Some of the rats were re-immunized and re-mated. In Table 1 the results of immunization of the 12 female rats of the experimental animals are summarized. The figures in parentheses represent re-immunization and re-mating. The corresponding findings of 10 control animals are also shown in Table 1.

Comparison between experimental and control shows little difference, although there is a slight decrease in the number of new-born in the immunized animal, and the average weight of each new-born rat is slightly less. No attempt was made at this time to evaluate the effect of prolonged immunization although some rats in both groups were re-immunized and re-mated, and in those that did conceive the new-born rats were not affected. Morphological and histological evaluation of the hearts, livers, and spleens of the new-born rats showed no evidence of abnormal development, or tissue injury. It appears from these preliminary observations that immunization on a short-term basis of adult female rats with homologous rat heart tissue is ineffective in interfering with normal cardiac formation or development of the fœtus. To establish whether or not immunization had occurred in the adult female rats, re-immunization at the end of the experiment (6 months) was carried out and 3 weeks post-re-immunization the animals were killed and their hearts, livers and spleens were removed, washed free of blood, blotted and the hearts and spleens weighed. A portion of each tissue was fixed for histological sections and the remainder minced and extracted for immunological examination against serum of each immunized animal. The control animals were treated in the same manner. The mean weights of the hearts were: experimental 1·0913 g (range 0·920–1·2672); control 1·0811 g (range 0·9613–1·4065) with a standard deviation of 0·123 g. The average weights of the spleens were: experimental 0·6841 g (range 0·5328–1·0008); control 0·6942 g (range 0·5617–0·9205) with a standard deviation of 0·135 g. No evidence of tissue change differing from control was found by gross or microscopic examination. Serological investigations with gel-diffusion technique of Ouchterlony[4] in which extracts of heart, spleen, and liver of each animal was tested against serum from experimental animals and controls gave negative results. A more sensitive system, consisting of kaolin particles, coated with the tissue proteins and reacted with serum of experimental and control animals also gave negative reactions. (Kaolin utilized in a particle agglutinating system developed in the authors' laboratory for detection of thyroid antibodies is a sensitive indicator of serological reaction. Kaolin actively absorbs protein at *p*H 5–7, and when washed and preserved with albumin forms a stable particle suspension the agglutination of which is readily apparent both macroscopically and microscopically.) In both systems rabbit anti-rat heart antibody gave strong positive reactions.

No detrimental effect of short-term immunization was apparent either on the mature female rats or her offspring. Gross and microscopic examination of heart, spleen and liver of the immunized mature rats and their offspring gave no evidence of changes attributable to the process of immunization. The short-term immunization procedure was selected with the thought in mind that a very minimal antibody production would be sufficient to disturb the embryological development of the heart. It is quite possible that the antigens of the embryonic heart are not susceptible to antibodies prepared against mature adult hearts. Failure to demonstrate serological evidence of immunization may explain the failure of impaired cardiac and fœtal development subsequent to short-term immunization of pregnant rats. Glueckssohn-Waelsch[7] produced abnormalities of nervous system development in embryonic mice from *DBA*/1 *Jax* strain mothers injected with mouse-brain and adjuvant prior to mating. Mothers of the same strain of mice injected with mouse heart and adjuvant in contrast to brain did not mate readily, and many matings were sterile but no cardiac abnormalities of embryos were found. Fertility appeared to be impaired in our experimental animals, but the series is too short to substantiate Glueckssohn-Waelsch's observation. The mothers, in her investigations, in contrast to ours, received several weeks of antigen injection prior to mating, but serological evidence of immunization was not studied. In later work[8] she did show positive precipitin reaction in 7 of 10 mothers immunized with brain tissue. Ebert[9] demonstrated preliminary indications of specific effects of antiheart and antispleen sera on differentiation of mesodermal elements of the chick blastoderm. The question of action of organ specific antibodies against fœtal tissue during development requires further investigation. The problem of antiheart antibodies is being re-investigated with prolonged immunization and utilization of antisera prepared against rat-heart in the rabbit. Evidence of antibody formation utilizing these systems may facilitate understanding of specific heart antiheart antibodies and clarify the effects such antiserum might have on the development of the heart as well as general embryonic development.

PATHOLOGY

Quantitative Technique for Uniform Tumour Implantation by Trocar in Gel-foam

Tumour transplantation in animals by injection of tumour fragments or tissue mince does not offer a quantitative method of implanting a known number of viable cells. Cell suspension techniques give the quantitative data but do not afford a uniform growth in a single implantation site. Often the injected fluid suspension spreads in the tissue and yields more than one tumour or a 'spread-out' tumour, the size of which is not a reflexion of cell count only.

The following method was devised to yield both the known cell count as well as single site of implantation with resulting uniformity of tumour growth.

Sterile methods are used in all procedures. Solid or ascites tumours are obtained from donor mice. Solid tumours are gently homogenized in a glass Dounce homogenizer or a cyto-sieve[1] with a 10-fold volume of sterile Locke's or other physiological diluent (1 g tumour plus 10 ml. diluent) containing 500 units penicillin and 50 units streptomycin per ml. The mechanical homogenization is accomplished by hand, using only six full strokes of the plunger with a coarse fitting Dounce homogenizer with a clearance of about 0·005 in. The resulting homogenate is allowed to sediment by gravity in an ice water bath for 10 min. The supernatant is removed with a syringe and 13-gauge trocar and transferred to a sterile vial. Aliquots are removed and treated with an equal volume of 0·5 per cent solution of eosin according to the method of Schrek[2]. Counts of the viable (non-stained) cells are made on a hæmocytometer. A minimum of 3 aliquots are counted, and if uniform, subsequent dilutions of the homogena[illegible] are prepared to yield the desired viable cell [illegible] The final dilution is recounted to [illegible] precision.

Sterile absorbable gelatine sp[illegible] the Upjohn Co., Kalamazoo, [illegible] tumour fragments. Microscopic examination of a fixed stained preparation of the cell suspension impregnated gel-foam fragment reveals the presence of tumour cells in the interstices of the gel-foam.

This technique is at present used by us for tumour propagation and has been used in several experiments in which a uniform single site implantation of a quantitated tumour cell inoculum was desired.

An experiment adopting the foregoing method was performed with 144 *C3H* mice using the mammary adenocarcinoma *H*2712. A cell suspension containing 50,000 viable cells per 0·1 ml. was prepared as here, absorbed on to the sterile gel-foam cubes and implanted by trocar subcutaneously in the supra-scapular area. A uniform tumour growth pattern resulted in the implanted mice. The latent period was 12–15 days from time of implant and the tumours, uniform in contour, achieved approximately equivalent sizes in all mice as tumour growth progressed.

This method adopting gel-foam impregnation has also been used by us for implantation of chemical carcinogens, as well as tumour cells, subcutaneously, intra-vaginally and in other anatomical sites.

Suppression of Experimental Allergic Encephalomyelitis by Cytotoxic Drugs

The action of cytotoxic drugs in experimental allergic encephalomyelitis is of interest in the examination of the mechanism of this disease in animals and may have therapeutic implications for auto-immune disease in man. Hoyer *et al.*[1] have shown that 6-mercaptopurine can suppress experimental allergic encephalomyelitis in rabbits and guinea pigs, but Field[2] has reported negative findings in the latter species.

In the observations described here, two compounds were tested for activity against experimental allergic encephalomyelitis and hæmolysin formation in the guinea pig—*cyclo*phosphamide ('Endoxana'), an alkylating agent, and 4-amino-*N*-methyl-pteroylglutamic acid ('Methotrexate'), a folic acid antimetabolite.

Guinea pigs weighing 200–500 g were sensitized with a single intradermal injection of homologous whole brain suspension, emulsified with an equal volume of complete Freund adjuvant (Difco). Each injection (0·1 ml.) contained 1 mg guinea pig brain (dry weight) and 0·1 mg M butyricum. *Cyclo*phosphamide 20 mg/kg/day and 'Methotrexate' 5 mg/kg/day were given intraperitoneally, while control animals received 1 ml. isotonic saline each day by [illegible] The interval between sensitization and [illegible]tion of drug administration, were [illegible] 1. In addition, those animals [illegible](1–24 days) were given 1 ml. [illegible]heep red cells subcutan-[illegible]olysin production.

Table 1. Effect of Cytotoxic Drugs on Experimental Allergic Encephalomyelitis

Days of treatment	No. of animals in group	Paralysed by day 17	Paralysed by day 22	Animals with histological lesions	
	5	5	5	5	Controls
	5	3	3	5	
	4	4	4	4	
	14	12	12	14	Total
1–24	5	0	0	0	*Cyclo*phosphamide
1–16	5	0	0	0	
1–8	5	0	2	4	
9–15	5	0	0	5	
	20	0	2	9	Total
1–24	5	0	0	0	'Methotrexate'
1–16	5	0	0	5	
1–8	5	1	4	5	
9–15	5	0	3	4	
	20	1	7	14	Total

the survivors killed 21–24 days after sensitization. The central nervous system was sampled by a complete sagittal section of the brain and spinal cord, and examined for histological evidence of experimental allergic encephalomyelitis—perivascular cuffing, meningitis, and subependymal infiltration. The hæmolysin titre of the serum was estimated using 4 *MHD* complement and an end-point of 50 per cent hæmolysis.

*Cyclo*phosphamide and 'Methotrexate' each suppressed the development of experimental allergic encephalomyelitis completely when given for the full 24 days of the experiment (Table 1). Following shorter periods of administration the disease was either totally inhibited (*cyclo*phosphamide 1–16 days), or the clinical manifestations were reduced and the onset of paralysis significantly delayed ($P < 0{\cdot}05$). Twelve of the 14 control animals were paralysed by the seventeenth day, compared with only 1 of the 40 treated animals. There was no apparent difference between those animals in which treatment was started on the day of sensitization, and those in which it was delayed until the eighth day.

The formation of hæmolysin to sheep cells was also suppressed by each drug (Table 2).

Table 2. Effect of *Cyclo*phosphamide and 'Methotrexate' on Hæmolysin Titres

Controls	*Cyclo*phosphamide	'Methotrexate'
512	<8	<8
512	0	0
256	0	0
128	0	0
128	0	0

All animals were submitted to post-mortem examination. Only one, on *cyclo*phosphamide, showed evidence of drug toxicity—multiple hæmorrhages into the viscera.

*Cyclo*phosphamide and 'Methotrexate' are known to inhibit a variety of immune responses in the guinea pig[3,4] and rabbit. The suppression of experimental allergic encephalomyelitis by these compounds may therefore be due to an effect on the immune mechanism itself, or alternatively to some non-specific anti-inflammatory action similar to that described for 6-mercaptopurine[5].

We thank Dr. Ruth Porter, of Lederle Laboratories, for the 'Methotrexate', and Dr. J. M. Simister, of Ward Blenkinsop and Co., for the 'Endoxana'.

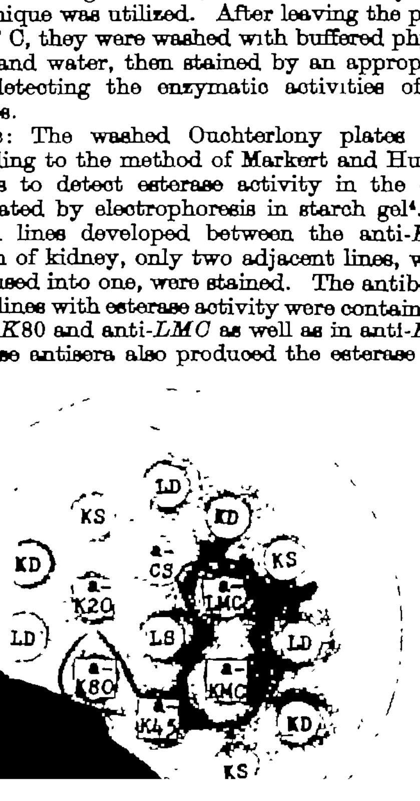
Enzymatic Activities of the Soluble Antigens in Kidney Microsomes

As revealed in the experiments using rat liver and chicken kidney, the microsomes consist immunologically of a number of different antigenic components[1]. On the other hand, it has become well known that the microsomal fraction contains many kinds of enzymes[2]. The question thus arises whether the immunologically resolved components may also differ from each other in enzymatic activity. In this communication we report that the activities of esterase and phosphatases are respectively localized in antigenically different components of the microsomes.

Adult chickens were used as the source of antigens for both injection and testing. Seven different types of antisera were prepared against rabbits. These were: (1) antiserum against liver microsomes (anti-*LMC*); (2) antiserum against kidney microsomes (anti-*KMC*); (3) antiserum against the proteins precipitated from deoxycholate-extract of kidney microsomes between 10 and 20 per cent saturation of ammonium sulphate (anti-*K*20); (4) antiserum against proteins precipitated between 25 and 45 per cent saturation (anti-*K*45); (5) anti-serum against proteins precipitated between 60 and 80 per cent saturation (anti-*K*80); (6) antiserum against unsedimentable post-microsomal fraction of kidney homogenates (anti-*KS*); (7) antiserum against chicken serum (anti-*CS*). The antibody patterns of these antisera, together with the procedures for separating the deoxycholate-extract of microsomes (*D*-fraction) into three immunologically distinct sub-fractions (*K*20, *K*45 and *K*80), have been communicated previously[3]. As the test antigens, *D*- and *S*-fractions were prepared from the livers and kidneys of freshly killed chickens.

For the immunological tests, the Ouchterlony agar diffusion technique was utilized. After leaving the plates for 36 h at 37° C, they were washed with buffered physiological saline and water, then stained by an appropriate method for detecting the enzymatic activities of the precipitin lines.

(1) *Esterase*: The washed Ouchterlony plates were treated according to the method of Markert and Hunter, who used this to detect esterase activity in the components separated by electrophoresis in starch gel[4]. Of 5–6 precipitin lines developed between the anti-*KMC* and *D*-fraction of kidney, only two adjacent lines, which occasionally fused into one, were stained. The antibodies to cause these lines with esterase activity were contained in anti-*KS*, anti-*K*80 and anti-*LMC* as well as in anti-*KMC* (Fig. 1). These antisera also produced the esterase lines



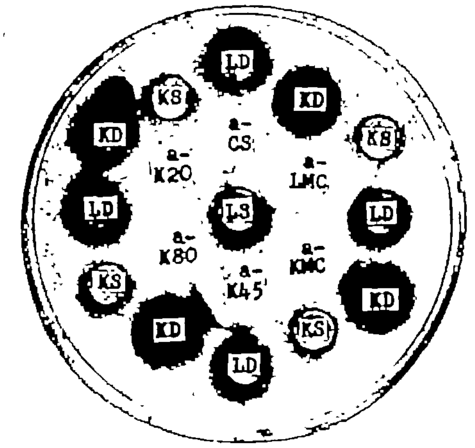


Fig. 2. Patterns of precipitin lines in Ouchterlony plate stained for detecting alkaline phosphatase activity. *KD*, *D*-fraction of kidney; *KS*, *S*-fraction of kidney; *LD*, *D*-fraction of liver; *LS*, *S*-fraction of liver; cf. text for symbols of antisera

in the reaction with the *S*-fraction of kidney or liver. Anti-*K*20 and anti-*K*45, however, contained few antibodies to give the precipitin lines with esterase activity. As previously reported, these antisera are highly '*D*-fraction specific'; that is, most of the antibodies which they contain are directed against the components predominantly distributed only in the *D*-fraction. Therefore, esterase activity should reside in the antigenic components identified to be 'non-specific' in the sense that they are found in common in both *D*- and *S*-fractions prepared from various organs. Anti-*CS* did not contain any antibodies to react with these components.

An aliquot of *D*-fraction of kidney was used for electrophoretic analysis with Smithies's starch gel method[5]. The run was made in borate buffer (0·01 M, *p*H 8·6) at a field strength of 11 V/cm for 7 h at 4° C. Following electrophoresis, the gel was longitudinally divided into two strips and one of them was stained to detect the component having esterase activity. A component with high mobility was stained. The other half of the gel was frozen, thawed and transversely cut into six small pieces. The deoxycholate-eluates from each piece were introduced into the respective peripheral wells of an Ouchterlony plate and allowed to diffuse against the antiserum filling the central well. Only the eluate of the piece which was taken from the locus corresponding to the site of esterase activity in the stained half gave rise to a stainable precipitin line in the reaction with anti-*KMC*, anti-*K*80, anti-*KS* and anti-*LMC*.

(2) *Phosphatases*. The washed Ouchterlony plates were stained with a solution containing α-naphthylphosphate and fast blue *BB* salt at *p*H 9 (with 0·05 M barbital buffer) for alkaline phosphatase and at *p*H 5 (with 0·2 M acetate-buffer) for acid-phosphatase[6]. Of the antisera used, only anti-*KMC* and anti-*K*45 produced the line which stained for alkaline phosphatase (Fig. 2). As shown in the earlier paper[3], anti-*K*45 is not only '*D*-fraction specific' but also highly 'kidney-specific', and this antiserum produced several lines, with the *D*-fraction of kidney only, in the unstained plates. The result does not directly imply that the component with alkaline phosphatase is 'kidney specific', because, after histochemical treatment, an identical stained line became detectable, though very faintly, between anti-*K*45 and the *D*- and *S*-fractions of liver. Faint lines were also detectable between anti-*KMC* and the *S*-fraction of kidney and liver. This fact suggests that the application of histochemical methods might make visible some of the precipitin lines otherwise left undetectable.

The lines positive for acid phosphatase were always very broad, and this made it difficult to identify precisely the stained components in the Ouchterlony plate, but it is fairly certain that the same lines positive for alkaline phosphatase were also stained at *p*H 5. Two stained lines sometimes appeared between anti-*KMC* and the *D*-fraction of kidney.

In the electrophoresis of the kidney *D*-fraction with starch gel, a component with low mobility is found to be positive for phosphatases staining, but elution of this component from the gel to permit testing it with the Ouchterlony plate has so far been unsuccessful.

The results described here indicate that the activities of esterase and the phosphatases reside respectively in immunologically different components of the microsomes, but they do not immediately prove that each immunologically resolved component corresponds to a different enzyme species. It might occur that multiple antigenic components display the same enzyme activity. Reciprocally, one antigenic component could display the activities of multiple enzymes, as was suggested in the case of acid and alkaline phosphatases.

It is doubtful whether the antibodies utilized here are directed against the enzymatically active groups of the molecules in the microsomes. Judging from the fact that the precipitin lines could be well stained, it seems to be conceivable that the antigenically determinant groups for producing the present antisera do not always coincide with the enzymatically active sites of esterase or phosphatases.

Proteolytic Activation of Glucose-6-phosphatase in Normal, Diabetic and Hepatomic Rat Livers

Phosphorylation of glucose, the hexokinase reaction, is an irreversible one which, however, is reversible by a specific phosphatase, the glucose-6-phosphatase (G-6-pase). Therefore the velocity of the phosphorylation of glucose is not only dependent on the activity of the hexokinase, but is also a result of the contrary action of both the enzymes. It was shown by some authors[1,2] that the activity of G-6-pase is different in varying conditions of metabolism. Tissues or cells with a high catabolism of carbohydrates show a significantly decreased activity of G-6-pase, besides an increased activity of hexokinase[2]. Highly glycolysing tumours represent tissues with a remarkable catabolism of carbohydrates and also show a decreased activity of G-6-pase[3,4]. Hitherto no tumour has been found with a noticeable activity of this enzyme. On the other hand, it will be expected that tissues with a diminished consumption of glucose or increased synthesis of glucose from non-carbohydrate sources via the Embden–Meyerhof pathway exhibit an enhanced activity of G-6-pase. Accordingly Mokrasch[1] found increased activity of phosphatase in diabetic liver.

Freedland and Waisman[5] showed that *in vitro* the activity of G-6-pase can be increased by incubation with papain. The authors suppose this process to be a result of a proteolytic activation of the enzyme in consequence of the splitting of proteins or polypeptides as mascating substances from the molecule of the phosphatase. We found that activity of G-6-pase could be enhanced also by incubation of the enzyme with trypsin and for this reason we suppose that the proteolytic activation is an unspecific process[6]. Based on these theoretical considerations we were interested in examining the proteolytic activation of the G-6-pase on the different conditions of metabolism and to compare the rate of alteration of its activity. Also we hoped to consider whether the rapid raising of the activity of the enzyme during the development of a diabetes mellitus is based on a 'demascation' similar to the proteolytic activation of the G-6-pase *in vitro*. In this case, a lower proteolytic activation should be expected in the G-6-pase from diabetic liver than in the enzyme from normal liver.

On the other hand, the diminished activity of the enzyme in tumours could be explained by 'mascating' processes during the carcinogenesis. Accordingly in this case one can expect an increased proteolytic activation of the enzyme from tumours in comparison with corresponding normal tissues.

Therefore we examined the possibility of a proteolytic activation with trypsin of the G-6-pase from normal and diabetic liver and from hepatoma. Diabetes mellitus was produced in white Wistar rats by injection of 7 mg alloxan in saline. In order to control the diabetogenic action of alloxan we determined the blood sugar of the rats by means of enzymatic tests with glucose oxidase. Hepatoma was produced by feeding with 5 mg dimethylaminoazobenzene (butter yellow) daily for 200 days.

The G-6-pase is bound to the microsomes and therefore we carried out proteolytic activation in a homogenate of liver and also in isolated microsomes[7]. Proteolytic activation was carried out by incubation of the samples (homogenate or microsomes) with trypsin and inhibition of the action of trypsin by 'trasylol' (trypsin–kallikrein inhibitor, Bayer-Leverkusen) in the described manner[8]. We determined the activity of the G-6-pase by the method of Freedland and Harper[9] and the proteins by the biuret method. Absolute activity is defined as micromoles phosphate liberated/h in 1-ml. samples; specific activity as micromoles phosphate liberated/h and 1 mg protein at 37° C. Comparing the proteolytic activations we used the specific activity because in this case the occasional effects of dilutions were eliminated.

The results are summarized in Table 1: they are mean values of 4–6 experiments.

Table 1. COMPARISON OF THE PROTEOLYTIC ACTIVATION OF THE GLUCOSE-6-PHOSPHATASE IN NORMAL AND DIABETIC LIVERS AND HEPATOMA

	Normal liver	Diabetic liver	Hepatomic liver
Homogenate			
Initial absolute activity	187 ± 6·08	218 ± 7·00	57 ± 18·1
Absolute activity after proteolytic activation	312 ± 10·5	349 ± 11·5	52 ± 11·0
Increase (per cent)	67	60	−10
Initial specific activity	1·01 ± 0·05	1·67 ± 0·31	0·55 ± 0·24
Specific activity after proteolytic activation	3·42 ± 0·75	5·61 ± 0·10	0·41 ± 0·12
Increase (per cent)	268	238	−30
Microsomes			
Initial absolute activity	179 ± 4·12	240 ± 8·42	53 ± 15·0
Absolute activity after proteolytic activation	266 ± 15·1	334 ± 44	53 ± 18·3
Increase (per cent)	49	40	+0
Initial specific activity	2·43 ± 0·20	3·21 ± 0·45	1·12 ± 0·23
Specific activity after proteolytic activation	6·68 ± 0·39	7·67 ± 0·69	0·39 ± 0·07
Increase (per cent)	175	140	−65

Absolute activity, μmoles phosphate liberated/ml. h. Specific activity• μmoles phosphate liberated/mg protein h.

It can be seen that proteolytic activation of G-6-pase from diabetic liver compared with normal liver is not increased significantly. Also these results exclude a partial 'demascation' of the enzyme during the developments of the diabetic metabolism. On the other hand, similar experiments carried out by us[10] with fructose-1,6-diphosphatase (FDPase), which also acts irreversibly in the catabolism of carbohydrates, showed a partial 'demascation' of FDPase during the development of a diabetes. For this reason increase of activity of G-6-pase could be explained either by a two-step-mechanism of activation or by the existence of two isoenzymes of G-6-pase or by a *de novo* synthesis of the enzyme after the application of alloxan.

Also the results of a diminished or absent proteolytic activation in the hepatoma exclude a possible 'mascation' of the phosphatase during carcinogenesis. Since the carcinogenesis represents a long-acting process, the destruction of the enzymatic activity and an inhibition of the *de novo* synthesis during the development of a hepatoma is more probable. We consider the very low absolute and specific activity of G-6-pase in hepatoma as evidence of this.

Enzymatic Dedifferentiation of Neoplastic Cells

VARIOUS authors have suggested that the enzymatic equipment of neoplastic cells need not necessarily be immutable and that it may show variations as the result of a number of completely unknown influences. This communication describes a striking example of enzymatic dedifferentiation recently observed in a chemically induced squamous cell carcinoma subjected to serial transplantation by various routes. The logical consequence of such an observation is to make us aware of how fragile are the grounds accepted as bases for the procedures at present in use for screening compounds as anti-cancer agents.

In this investigation squamous cell carcinoma was induced in the cervix and upper vagina of adult virgin *C3H/N* mice by twice-weekly painting of the ectocervix with a 1 per cent suspension of 3,4-benzpyrene in acetone. After fewer than 40 treatments all the animals showed invasive neoplasms. A squamous cell carcinoma, provoked by this method and serially transplanted under the skin of mice of isologous strain, was studied histochemically from the 79th to the 102nd transplantation generation. An ascites line, adapted from a benzpyrene-induced cervico-vaginal squamous cell carcinoma[1], was examined in its 280th to 287th transfer generations. The tumour was maintained by injecting ± 13 × 10[6] freely growing neoplastic cells into the peritoneal cavity of adult virgin *C3H/N* mice. The animals were killed from 7–9 days after inoculation. Solid transplants were obtained by subcutaneous injection of inocula (from passages 282–285) of the same magnitude. All the animals were killed by breaking their necks. The genital tracts of painted mice and the solid subcutaneous nodules were carefully dissected out, frozen with carbon dioxide, and cut serially (10μ) in a cryostat.

Smears were prepared from ascites fluid and kept in a refrigerator at −20° C. Smears and tissue sections were treated for the demonstration of cellular activity of 5-nucleotidase[2]. Although in normal cervico-vaginal epithelium of the mouse slight cyclic variations in the activity of 5-nucleotidase were observed, the over-all tissue activity of this enzyme is weak. Pathological, non-invasive (hyperkeratosis, dysplasia, *in situ* carcinoma) epithelium shows the same weak enzymatic activity except for its cornified layers. Invasive squamous cell carcinoma (early stromal invasion, micro- and macro-carcinoma), on the other hand, shows a constantly high activity of 5-nucleotidase in all its component cells[3]. Necrotic portions of the tumour, horny material, and poly-nuclear leucocytes show some degree of enzyme activity, whereas macrophages are inactive. The constantly high 5-nucleotidase activity typical of malignant squamous cells and also found in vaginal washings from animals bearing benzpyrene-induced cervico-vaginal carcinoma has been considered to be of definite diagnostic value[3].

The pattern of reactivity of the solid transplantable squamous cell carcinoma is strikingly similar to that found in the mother tumour, and does not vary with prolonged transfer.

The situation in the ascites line of such chemically induced cervico-vaginal carcinoma is entirely different. There is a complete absence of 5-nucleotidase activity in the tumour cells floating freely in the ascites fluid as well as in those so closely packed as to form solid subcutaneous tumours. Clusters and/or sheets of tumour cells, equally devoid of enzyme activity, were found infiltrating the subcutaneous muscle layer, the lymph nodes, and the liver sinuses.

Thus we observe a truly remarkable sequence of events. In the course of chemical carcinogenesis the activity of 5-nucleotidase suddenly increases in the squamous genital epithelium of the mouse, a fact which in itself is in distinct contrast to the activity of most of the enzyme systems studied. Moreover, this phenomenon is stable when the chemically induced carcinoma is transferred serially to the subcutaneous tissues, and remains unaltered notwithstanding long-continued transferring. On the other hand, ascites tumour cells derived from these structures show an equally remarkable drop in their enzymatic content: 5-nucleotidase activity is entirely absent and no rebound effect is found when such cells are grown as solid subcutaneous nodules. Thus it is clear that these two transplantation routes generate neoplastic cells the enzymatic equipment of which is of a different nature. Screening procedures used in cancer chemotherapy often make use of ascites tumour forms.

The example presented here makes it obvious that care must be taken when interpreting data based on such material, that is, observations based on an ascites line should not always be extrapolated to the tumour from which this line was adapted. Although solid transplantable carcinoma of the mouse cervix may prove a valuable tool for such screening purposes, the ascites line derived from it, which for reasons all too obvious was thought to be even more valuable, has not fulfilled its promise. However, by illustrating the process of enzymatic dedifferentiation, the ascites tumour has nevertheless proved to be worth while studying.

We thank Dr. I. Koprowska, Philadelphia, who kindly provided us with the original solid transplantable tumour and its ascites form *MT*–890.

BIOLOGY

Activity of Gibberellin '*D*' on the Germination of Photosensitive Lettuce Seeds

Recent discoveries in the gibberellin series have brought to light a large number of new compounds the activity of which varies widely in different tests[1]. In particular, Hashimoto and Yamaki[2] with tobacco seeds, and Toole and Cathey[3] with lettuce seeds, reported that GA_4 was much more active than GA_3, while Brian *et al.*[1] indicate that GA_4 and GA_7, which had about equal activity on lettuce seeds, were both more active than GA_3. However, the latter group stated that they were "not able to establish a simple relationship between dose and response" in their test. Borriss and Schmidt[4] crystallized a gibberellin preparation from cultures of *Gibberella fujikuroi* which was 30 times as active as GA_3 on the germination of *Diplotaxus* seeds and up to 2,000 times more active than GA_3 on seeds of *Lepidium ruderale*. Later this preparation, first called gibberellin A_8 or '*D*' (ref. 4), was found to be a mixture of GA_4 and GA_7.

Through the courtesy of Prof. H. Borriss we have been able to test a sample of his purified material on Grand Rapids lettuce seeds under our conditions[5] and find it indeed to be of extremely high activity. This communication reports relative activity determinations and the interaction with the red/far-red system.

The tests were carried out with the shaking method previously described, duplicate samples of 50 seeds each in 2 ml. of solution in a 5-cm Petri dish at 25° C being used[5]. All manipulations were carried out rapidly under green light, but otherwise the seeds remained in absolute darkness throughout. The seeds for the present experiments unfortunately gave 30–40 per cent germination in darkness, as against less than 5 per cent in those previously used. However, their response to red and far-red light was the same as in the earlier lot, that is, 1-min exposure to either light produced the maximum effect. Gibberellins were prepared as stock solutions of 50 p.p.m. ('*D*') or 100 p.p.m. (A_3) in distilled water, and dilutions made from these just before use.

Fig. 1 shows that in comparative tests the activity of gibberellin '*D*' $(=GA_4+GA_7)$ is almost exactly 100 times as great as that of GA_3. The differences between the two curves, apart from the 100 times difference in absolute values, are probably not significant. The curve for GA_3 confirms in detail our previous data (Fig. 3 of ref. 5). The very high ratio of activities is remarkable, for although GA_7 is more active than GA_3 in several tests, it is usually so only by a factor of 2–3. It is reported as being only twice as active as GA_3 on the lettuce hypocotyl[1]. All in all, the unusually high ratio suggests a synergism between the two gibberellins.

These findings raise again the problem of whether light might act by releasing a gibberellin in the seed. It had been concluded that this is not the case[5], because: (*a*) the action of GA_3 could not be reversed by far-red; (*b*) light-treated seeds yielded no detectable increase in gibberellin. The latter tests were carried out on dwarfs 1 and 5 of corn, which fortunately are highly sensitive not only to GA_3 but also, and about equally so, to GA_4 and GA_7 (ref. 1). If light had acted to release appreciable amounts of GA_4 or GA_7, these substances should therefore have been detected in the tests, so that the doubts raised by Toole and Cathey[3] are not justified. On the other hand, the very high relative activity of the combination of GA_4+GA_7 found here might reopen the possibility of a liberation of both these in amounts below the threshold of the corn response, though adequate for germination of lettuce seed.

The influence of far-red on the germination caused by gibberellin '*D*' was, therefore, examined as follows. The seeds were soaked in a series of concentrations of '*D*' or GA_3 in the dark, and subjected to 5-min far-red light (about 30 ft.-candles) at 1·5 h after the beginning of soak-

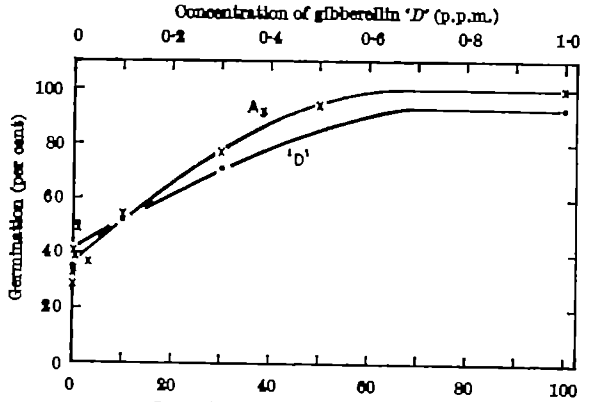

Fig. 1. Effect of gibberellin '*D*' or A_3 at various concentrations on the germination of Grand Rapids lettuce seeds in darkness

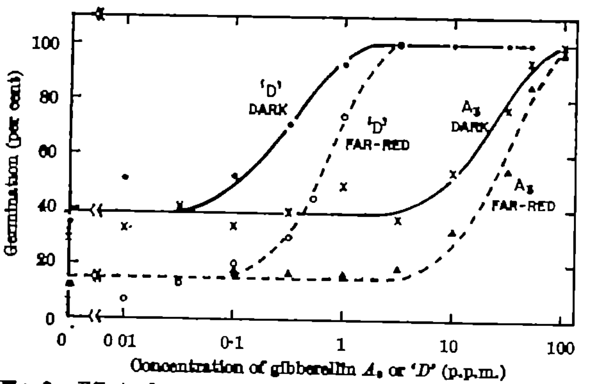

Fig. 2. Effect of 5-min far-red light on the germination of Grand Rapids lettuce seeds soaked in various concentrations of gibberellin '*D*' or A_3. Far-red light given at 1·5 h after the beginning of imbibition. Solid lines, far-red treatment: dotted lines, dark control (same as Fig. 1)

ing. This was previously shown to be the most sensitive time[5]. Germination was then determined 2 days later. Fig. 2 (in which the concentrations are plotted on a logarithmic scale) compares the germination with that obtained in complete darkness. It is seen that the far-red decreased the germination of the dark controls by almost 20 per cent. It decreases the germination of the seeds treated with low concentrations of either of the gibberellins by essentially the same amount. The curve for GA_3 extends to lower concentrations the data previously given for 100 p.p.m. (Tables 2 and 3 of ref. 5). At higher levels of both gibberellins the effect of the far-red disappears. At 3 p.p.m. gibberellin '*D*', indeed, the germination was 100 per cent with or without far-red exposure.

The conclusion that the action of gibberellin is not in the least reversed by far-red light is open to the reservation that the gibberellin might continue to act after the far-red exposure[6]. This difficulty was previously dealt with by limiting the GA_3 treatment to 2 h or less[5]. It was dealt with in another way by Haber and Tolbert[7], who transferred the seeds to 37° after exposure to far-red, since GA_3 does not promote germination at 37°. They found no reversal by far-red, but unfortunately their seeds germinated incompletely (only 39 per cent). In the present experiments the seeds were soaked in gibberellin '*D*' for 2 h, beginning 2 h after the onset of soaking. Thereafter the gibberellin was washed off and the seeds returned to water. To ensure maximum possible effect of the far-red the exposure was lengthened to 1 h, given either just before or just after the gibberellin '*D*'.

Table 1 shows that the far-red again decreased the control germination by 17 and 24 per cent respectively. The germination expected in gibberellin '*D*', calculated from this effect on the water controls, is shown in the last column. The agreement is good. It may be concluded, therefore, that *the action of gibberellin 'D' is not reversed by far-red*.

Table 1. Effect of 1-h exposure to far-red light on germination of Grand Rapids lettuce seeds treated with gibberellin '*D*' (3 p.p.m.) for 2 h. Gibberellin '*D*' treatment for 2 h begun 2 h after the beginning of soaking. 1-h exposure to far-red light given immediately before or after the gibberellin treatment, while seeds were soaked in water. Germination determined at 48 h after gibberellin treatment

Treatments				Germination (per cent)	
←Water→			←Water→		
1 h	1 h	2 h	1 h	Experimental	Expected
	—	Water	—	31	—
	FR	Water	—	14	—
	—	Water	FR	7	—
	—	Gibberellin '*D*'	—	62	—
	FR	Gibberellin '*D*'	—	42	45
	—	Gibberellin '*D*'	FR	32	38

Is there any other way in which the action of red light could be accounted for in terms of the release of gibberellin? In general, the effect of red light on germination can be reversed by far-red up to at least 8 h following exposure. The gradual onset of irreversibility is often referred to as the 'escape curve'. If red light were to liberate gibberellin, this curve would be in reality the curve showing gibberellin release. However, such an interpretation is exceedingly improbable because: (*a*) the gibberellin so released would as noted here have to be even more active than either constituent of gibberellin '*D*' to have escaped detection on corn dwarfs 1 and 5; (*b*) it would only be beginning to appear in the seed more than 3·5 h after soaking, which is a time of greatly lowered sensitivity[5]. It may be noted, too, that in stem elongation and the flowering of short day plants the effects of red light could scarcely be due to the liberation of gibberellin, since they act in the opposite sense.

Thus we conclude that gibberellin, instead of being a product of red light, must initiate one of the chemical reactions which result from the primary light reaction.

This work was supported by a grant No. *G*9084 from the National Research Foundation. We thank Prof. Heinrich Borris of Greifswald for a sample of his gibberellin '*D*'.

Influence of Crop Residue Decomposition Products on the Germination of *Fusarium solani* f. *phaseoli* Chlamydospores in Soil

Fusarium solani f. *phaseoli*, the cause of stem and root rot of bean, has been shown to exist in nature primarily in the form of chlamydospores[1]. Such chlamydospores germinate on the addition of various sugars or amino-acids but not ordinarily when water alone is used[1]. The chlamydospores have also been shown to germinate in the presence of exudates of the host and various other plants[2,3]. Evidence is presented here to show that substances produced during the decomposition of crop residues under natural field conditions can also influence the germination of chlamydospores in the absence of exudates from living plants.

In these studies, chlamydospores were obtained by adding nutrient-media-free macroconidia to non-sterile soil[1]. Details of the procedure in obtaining the substances from decomposing plant residues are published elsewhere[4].

Briefly, the substances were obtained as cold water extracts from the plant residues which had been freed of the surrounding field soil prior to the extractions. Plant debris, soil particles and micro-organisms were removed from the extracts by ultra-centrifugation and tests were carried out immediately after the extraction to minimize possible changes in the activity of the extracts. Aliquots of about 3 g of the air-dried soil containing chlamydospores were saturated with the test extracts and extent of germination was determined after 24 h by microscopic examination of acid-fuchsin-lactophenol-stained soil smears. In the controls, distilled water was used in the place of the extracts. The results of a typical series of observations are given in Table 1.

Table 1. EFFECT OF DECOMPOSITION PRODUCTS ON GERMINATION OF CHLAMYDOSPORES OF *F. solani* f. *phaseoli* IN NON-STERILE SOIL

Source of test extract (days)	Germination rating	Source of test extract	Germination rating
Rye 0*	+ + †	Broccoli 0	–
10	+	7	+ +
18	0	16	+ +
25	0	24	+ +
Barley 0	+ +	Broad bean 0	+ +
10	+	10	+ +
17	+	18	+ +
24	+	25	+ +

* Type of plant residue and number of days it had been decomposing in the field prior to extraction. Rye and barley turned under when crop was heading out, broccoli and broad bean after harvest.

† Amount of germination rated as 0, +, + +; none, fair and good, respectively; see Fig. 1, which shows a '+ +' rating. No germination of chlamydospores was obtained in the controls in which distilled water was used in place of the various test extracts.

Extracts from all four crop residues used stimulated germination of the chlamydospores. Differences were noted between the various extracts, however, in the intensity of stimulation of the chlamydospore germination that was obtained and the subsequent vigour of growth of the germ-tube hyphæ. In general, two types of response were obtained. Some extracts induced vigorous germination of the chlamydospores followed by extensive growth of the germ-tube hyphæ (Figs. 1 and 2). The germ-tube hyphæ were large, stained well and appeared vigorous. The second, and perhaps most interesting, response was a stimulation of chlamydospore germination which was soon followed by lysis of the germ-tube hyphæ (Fig. 3). Some of the extracts did not appear to have any effect on chlamydospore germination since no stimulation was obtained. The aforementioned differences in response appeared to depend on the types of residues used and their decomposition periods in the soil. Highly active extracts were most frequently obtained from the residues during early stages of decomposition. The stimulatory effect of the rye and barley extracts appeared to be weaker and of shorter duration than in the case of broccoli and broad bean, and extracts from the latter two crops continued to stimulate the germination of chlamydospores even after the residues had been decomposing in the soil for up to 25 days. The extracts from rye and barley residues also gave more instances of germ-tube lysis. Since only a limited number of extracts were tested, however, the precise relationship between type of residue, decomposition period and chlamydospore germination could not be determined at this time.

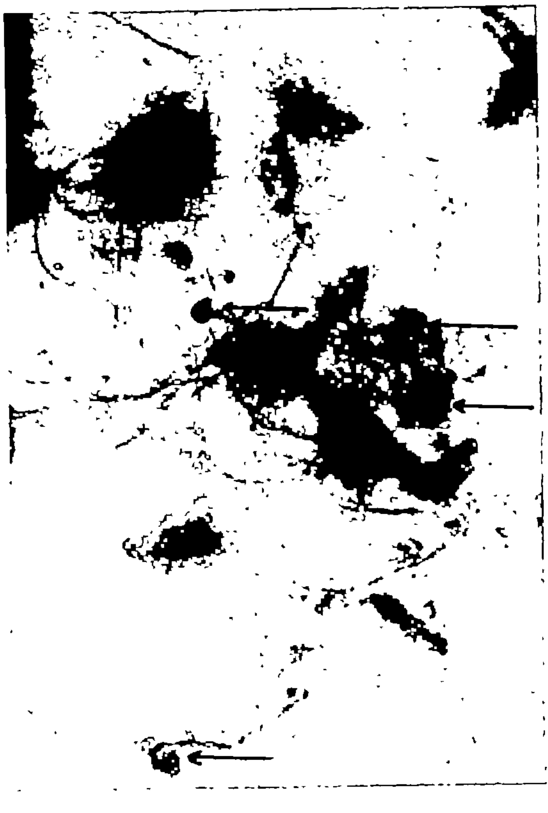

Fig. 1. Extent of chlamydospore germination of *F. solani* f. *phaseoli* in soil placed in contact with broccoli residues which had been decomposing for 7 days in the field. This amount of germination would have a + + rating. Arrows indicate germinated chlamydospores

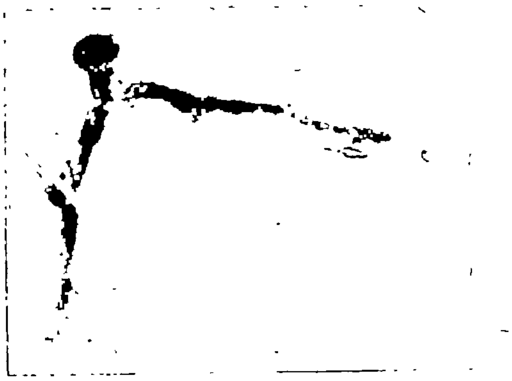

Fig. 2. Vigorously growing hyphæ arising from chlamydospore in contact with the broccoli residue; compare with Fig. 3

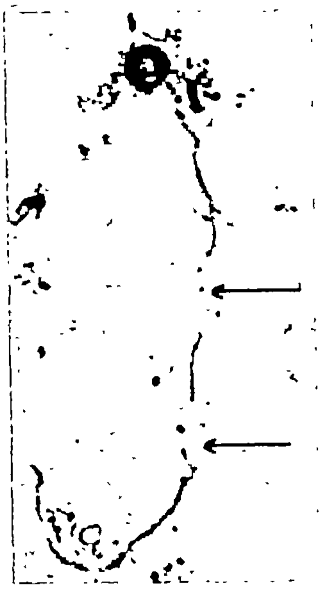

Fig. 3. Germination of chlamydospore in contact with barley residues which had been decomposing for 10 days in the field. The germ tube is thin and lysis of the contents has occurred in two areas indicated by arrows

To approach more closely conditions in Nature, partially to obviate the dilution problem and the possibility that results obtained with extracts could be due to artefacts in the extraction procedure, tests were also carried out with fragments of intact plant residue that had been decomposing in the field for various periods of time. In these tests, fragments of decomposing residue were covered with the previously mentioned soil containing the chlamydospores and moistened with water. Soil smears were prepared 24 h later of the soil in direct contact with the plant residue. Staining and extent of chlamydospore germination were evaluated in the same manner as with the extracts. The results obtained in these tests were in close agreement with those obtained with the extracts. Germination of chlamydospores, however, was stimulated only in close proximity to the residue fragment and no germination could be detected in the soil not in contact with the residue.

The results described have interesting implications with respect to factors in the soil which can influence the germination and survival of infecting propagules of the soil-borne pathogen, *Fusarium solani* f. *phaseoli*. It is evident, too, that substances produced during the decomposition of plant residues can be active in the support of a biosphere in the soil which in some instances and under certain conditions may rival in importance that around the roots of living plants in maintaining, increasing or decreasing the population of active propagules of a pathogen such as *F. solani* f. *phaseoli* and perhaps other soil-borne plant pathogens.

Tissue Hydroxy-cinnamic Acids and Soil Moisture Stress

The stem tissue of pineapple plants (*Ananas comosus*, var. Cayenne) contains appreciable amounts of hydroxy-cinnamic acid derivatives ('phenolics'), largely as a quinic acid ester of *p*-coumaric acid[1,2] and an ester of ferulic acid. These phenolics are implicated in the metabolism of the plant growth hormone, indolyl-3-acetic acid[3,4].

This communication will present evidence that the amount of these phenolics in pineapple stem tissue is inversely related to the soil moisture content. This observation has obvious implications in connexion with various growth effects, including flowering, that may be affected by moisture stress.

The phenolics were extracted from 1–10 g of meristematic tissue from the stems of several plants by blending with water. In one experiment, they were then taken up in ethyl acetate after acidification of the aqueous extract. In the other experiments, the filtered aqueous extract was used directly. Similar results were obtained when the extractant was 2 per cent sodium dihydrogen phosphate or when the aqueous extract was boiled and filtered before spectrophotometry. These extracts showed a typical hydroxy-cinnamic acid spectrum with a maximum near 314 mμ (ref. 3); the absorbance per gram of tissue determined at this wave-length in the Beckman *DU* or *DK*-2 spectrophotometer quantitatively measured the stem phenolics.

The close inverse relationship between soil moisture sampled at the butt of the plant and stem tissue phenolics is evident from Fig. 1. The phenolics content fluctuated from week to week as the soil moisture-level varied with drought or rainfall. It is especially interesting to note that the relationship held even when the plant was presumably under only minor soil moisture stress. (A tension of 4 bar is equivalent to 28·0 per cent moisture in this soil; the wilting point of 15 bar is at 26·0 per cent soil moisture. Soil at the root zone has about 2 per cent less moisture than at the plant butt.) The results in Fig. 1 were for unirrigated plots, but even in adjoining plots receiving weekly irrigations to keep the soil moisture in the range 29–38 per cent, the phenolics curve showed a marked tendency to mirror the changes in the soil moisture curve from week to week.

It will be seen that the relationship is not merely a reflexion of tissue hydration under varying moisture stress. The phenolics calculated to a dry weight basis also show an inverse correlation with soil moisture (Fig. 1).

Table 1. CORRELATION OF SOIL MOISTURE WITH PHENOLICS IN STEM TISSUE OF PINEAPPLE PLANTS OR CROWNS (OAHU, HAWAII)

Sampling period	Field	r*	r†	No. of observations
Days 211–343, 1953	*A*	−0 41	−0·93	9
Days 204–338, 1957	*A*	−0 40	−0·76	10‡
Days 126–301, 1958	*B*	−0 87	−0·69	24
Days 126–301, 1958	*C*	−0 64	−0·54	24
Days 118–216, 1958 (crown stems)	*A*	−0 61	−0·02	15

* Correlation coefficient, phenolics versus soil moisture. The Field *B* results are those shown in Fig. 1.

† Correlation coefficient using soil moisture results two weeks previous to plant harvest.

‡ Using an ethyl acetate extract; other phenolics analyses were on aqueous extracts.

This observation of a close relationship between soil moisture and hydroxy-cinnamic acids in the growing point of the pineapple has been confirmed in experiments over several years (Table 1). In the first two experiments, covering a later period of the year than the 1958 tests, there seemed to be a lag of approximately two weeks before a change in soil moisture was reflected in the tissue phenolics content. When the correlation was for phenolics versus the soil moisture two weeks previously, the correlation coefficient was found to be −0·93 and −0·76 for the 1953 and 1957 experiments. In 1958, the best correlations were without the lag period in the soil moisture effect. In one test (Field *C*), an early wave of flowering occurred in early September. A good inverse correlation of −0·80 prior to flowering (17 samples) failed to hold once flowering was observed; the final seven observations showed a correlation coefficient of only

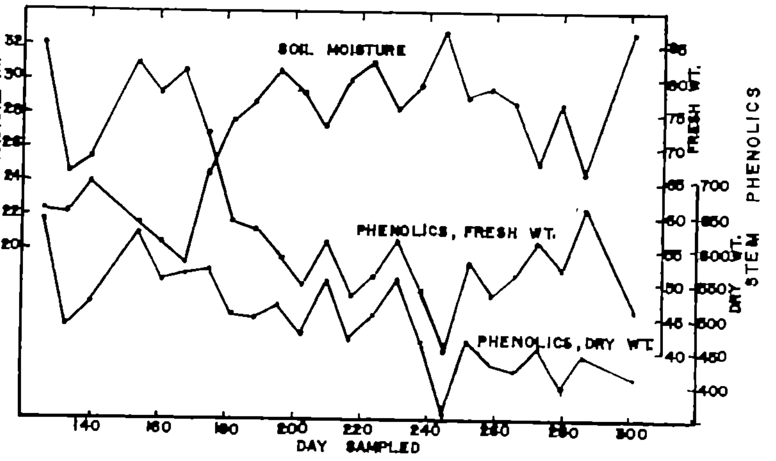

Fig. 1. Relationship of soil moisture and of phenolics in the stem tip of vegetative pineapple plants (Oahu, Hawaii, 1958). The phenolics values are absorbances at 313 mμ/g of tissue

+ 0·16 for stem phenolics versus soil moisture at the time of plant harvest.

Table 1 also gives the results of an investigation conducted by Dr. V. L. Singleton of these laboratories in which phenolics in the stem tissue of crowns of fruiting plants were determined. Even here we find the same inverse correlation with soil moisture which was observed for stem tissue of vegetative plants.

A similar correlation with other variables in the environment of the plant was not obtained. For example, radiation will bring about changes in soil moisture and might be suspected as being more directly involved, particularly in the phenolics variations in the fruit crowns. Yet the correlation coefficient for crown phenolics versus soil moisture was a significant − 0·61 (Table 1), whereas versus 'pan evaporation' it was an insignificant + 0·09. (Evaporation from a standard Weather Bureau pan is closely related to sunlight in pineapple areas.)

Owing to a change in research programme, I shall not be able to extend these observations to ascertain their significances in plant growth. It is hoped that reporting the available results at this time may interest other workers in determining whether tissue phenolics are responsive to soil moisture-levels in other plants, and whether growth effects such as flowering may be associated with the interrelationship reported here.

This article is published with the approval of the Director of the Pineapple Research Institute. I thank A. Fo, Martha Kent, Laura Aono, C. Farden and Nellie Oshige for assistance.

Occurrence of Dormant Ascospores in Soil

WARCUP[1] reported that steaming was a simple selective method for isolating Ascomycetes from soil. The method used, however, gave little indication of the temperature at which most soil fungi are killed and at which Ascomycetes survive. With the development of equipment by which steam–air mixtures at various temperatures may be obtained[2], it was decided to reinvestigate the heat tolerance of Ascomycetes in soil.

Initially several soils from tropical Australia known to contain high populations of Ascomycetes were used. When soil plates[3] were prepared from samples of these soils steamed at temperatures between 50° and 75° C for 30 min, it was noted that the number of colonies of some Ascomycetes was markedly higher than in plates prepared from unheated soil. Since the numbers of colonies on different soil plates are not strictly comparable the experiments were repeated using the soil dilution method.

An aliquot of soil (2·5–5·0 g) was added to a water blank to give a dilution of 1 : 100 and, after shaking, 1-ml. portions were placed in a series of Petri dishes. The bulk soil suspension was then heated in a water bath at 60° C for 30 min; immediately after its removal further dilution plates were made. All plates were poured with 'Dox' + yeast agar containing 30 μg/ml. streptomycin and 2 μg/ml. aureomycin to prevent growth of bacteria.

The results of an experiment with a grey-brown loam (soil *A*) from Koolpinyah, Northern Territory, Australia, are given in Table 1. The fact that more colonies are obtained after heating suggests that this treatment stimulates dormant spores in soil to germinate. Here we follow Gottlieb's definition[4] of a dormant spore as one which "does not germinate under the same nutritive and environmental influences which later allow production of germ tubes". Examination of the propagules[5] of young colonies developing on plates prepared from heat-treated soil showed that in many cases the previously dormant fungi were growing from ascospores. While dormancy in ascospores, particularly of certain coprophilous Ascomycetes, is well known[6], so far as we are aware dormancy of this type has not previously been considered in relation to soil fungi.

Since ageing is known to induce dormancy[6] and the soils examined had been stored dry for 10–20 years it is possible that the observed dormancy was a result of drying and storage, and might not occur in spores in normal, moist field soil.

Tests were made on moist soil immediately after removal from the field but here dormancy could not be so simply demonstrated. The number of propagules of many Ascomycetes in soil is low. This means that plates prepared at dilutions appropriate to record Ascomycetes are crowded with colonies of other fungi. While the heat-treatment used kills many fungi, allowing Ascomycetes to be easily seen, plates prepared from unheated soil are so crowded that it is difficult to decide whether lack of colonies of an Ascomycete implies its absence or only its suppression by the numerous other organisms present.

In attempts to overcome this problem various selective media, including an Actidione medium[7], were tried. None, however, proved of use for the organisms being studied. It was then decided to investigate the use of ethyl alcohol as a selective agent. Many Ascomycetes survive when soil is immersed in ethyl alcohol, whereas most other fungi are killed by this treatment[8]. In subsequent experiments 2·5 g of soil was immersed in 60 per cent alcohol for 6–8 min, then soil and alcohol added to a water blank to give a dilution of 1 : 100 (and an alcohol concentration of less than 1 per cent). Preparation of dilution plates and heat-treatment were then carried out as previously.

The results of a test with moist soil from a forest nursery at Belair, South Australia (Soil *B*), are given in Table 1. Alcohol-treatment reduced the number of colonies in this soil from 300,000 to 2,000–3,000/g; many of the alcohol-resistant fungi were Ascomycetes. The results in Table 1 show that although certain fungi were killed by the subsequent heating, this treatment stimulated others to germinate and increased the total number of colonies recorded.

Fungi, the spores of which have given evidence of heat-activated germination, include some members of the Sordariaceae, *Aspergillus fischeri*, *A. fischeri* var. *glaber*, *A. quadricinctus*, *Penicillium parvum*, *P. avellaneum*, *Anthracobia* sp., besides other unidentified Ascomycetes (including further Discomycetes). The Discomycetes isolated do not fruit on agar media, but fructifications were obtained on blocks of plaster of Paris. While most heat-activated spores are ascospores, in a few cases the propagule would appear to be some other unit (chlamydospore).

Most experiments on heat-activation of spores in soil have been made at temperatures of 60°–65° C for a standard time of 30 min. Temperatures as high as 85° C have been shown to activate spores but usually, depending on the fungus, such higher temperatures also kill some spores.

Table 1. EFFECT OF HEAT TREATMENT OF SOIL ON NUMBER OF COLONIES OF CERTAIN FUNGI ON SIX SOIL DILUTION PLATES

	No. of colonies			
	Sample 1		Sample 2	
Treatment	Nil	Heat	Nil	Heat
Fungus	Soil *A* (dry, stored)			
Thielavia (a)	15	0	14	0
Penicillium spp.	15	0	21	0
Aspergillus fischeri var. *glaber*	2	63	2	51
Total No. of colonies	41	78	50	62
	Soil *B* (moist, fresh)			
Chaetomium sp.	34	0	25	0
Thielavia (a)	5	0	6	0
Penicillium spp.	33	13	20	8
Humicola sp.	7	25	10	19
2/4*H*15	15	25	12	22
Aspergillus fischeri var. *glaber*	2	41	2	46
Aspergillus fischeri	0	9	0	15
Anthracobia sp.	0	5	0	7
3/4*H*117 (Pyrenomycete)	0	4	0	7
Eladia sp.	0	5	0	5
Gelasinospora sp.	0	8	0	3
Total No. of colonies	165	202	136	176

About half the soil samples so far examined have given some evidence of the presence of heat-activated dormant spores.

Determination of Distribution of Water in Wheat Grains by Interference Microscopy

It is of interest, especially in milling, to know the water content of different parts of grains, such as wheat. This communication describes a new method which permits the measurement of the water content with relatively high accuracy in every point of a microscopic section. The method is based on changes in refractive index of the tissue by water. The section is immersed in indane, a liquid with refractive index ($n_D = 1{\cdot}537$) similar to that of the dry tissue ($n_D = 1{\cdot}53$) and photographed in an interference microscope (Leitz) adjusted to give fringes in the field. Afterwards, the preparation is completely dried *in vacuo* (0·1 mm mercury, 96° C, 3 h), re-immersed in the liquid and photographed again in the interference microscope. The shift of the interference fringes (Fig. 1) between the two photographs, $\varphi_1 - \varphi_2$ (where φ, the optical retardation, = fringe distance × wave-length), enables the calculation of the water content in the following way: the amount of water per unit area m_w is given by $m_w = d \cdot \rho$, where d is the optical path length of water and ρ its density (1·00), so that $m_w = d$. Since the shift of the fringes:

$$\varphi_1 - \varphi_2 = d \cdot (n_i - n_w), \quad m_w = \frac{\varphi_1 - \varphi_2}{n_i - n_w}$$

where n_i is the refractive index of the immersion liquid and n_w that of water.

Since the value m_w depends on the section thickness, it is, in general, advantageous to relate the water content to the dry weight of the tissue. Dry weight m per unit area may be expressed in the form $m = \frac{\varphi}{\chi}$ (ref. 1), where φ is the optical retardation produced by the tissue. χ_w for grain sections containing mainly starch in water is 0·14 cm³/g (ref. 1). In our experiments the sections are immersed in indane with a refractive index of $n_D = 1{\cdot}537$. The corresponding χ_i is obtained by measuring the optical retardation of a section in water (φ_3) and in indane (φ_2) (dried section); χ_i is then $\frac{\varphi_2 \cdot \chi_w}{\varphi_3} = 0{\cdot}20$ cm³/g.[1] Thus the water content as a percentage of the dry weight can be represented by:

$$\frac{m_w}{m} \cdot 100 = \frac{\varphi_1 - \varphi_2}{n_i - n_w} \cdot \frac{\chi_i}{\varphi_2} \cdot 100 = 22 \cdot \frac{\varphi_1 - \varphi_2}{\varphi_2}$$

Best results can be obtained with sections 20–40µ thick made on a sliding microtome with an inclined knife at about 30° from the cutting direction. During sectioning the grains and the sections are covered with indane. Since this liquid is lipophilic, it prevents loss of water during the cutting and measuring processes. In order to obtain good penetration and efficient drying of the sections a volatile liquid has been chosen. Of all liquids tested indane has been most successful. Experiments have been performed to assess movement of water during sectioning and measuring. If the whole procedure is carried out within 10 min, no such movements can be detected.

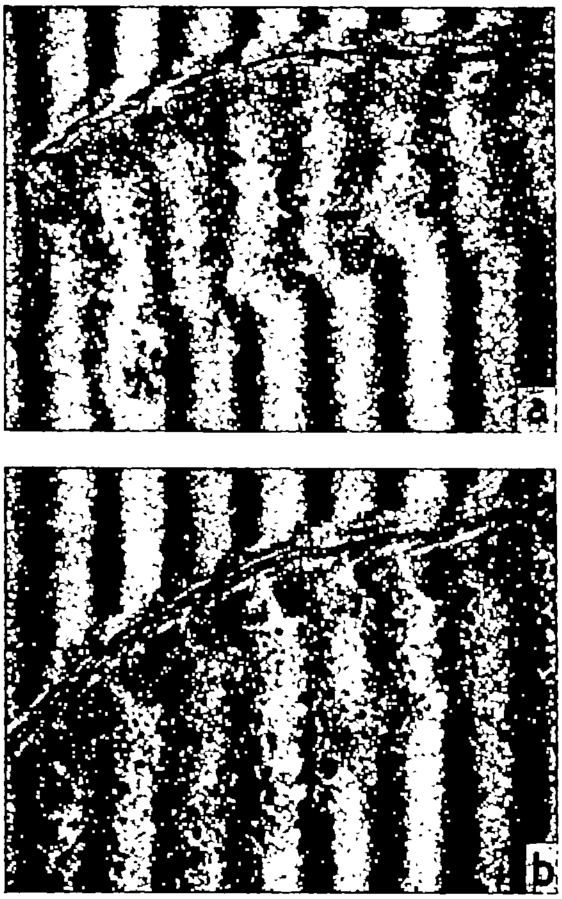

Fig. 1. Section of wheat grain, 30µ thick, with interference fringes. *a*, Before, *b*, after, drying

With experiments, in which sections of wheat and wheat meal are exposed to air containing different amounts of

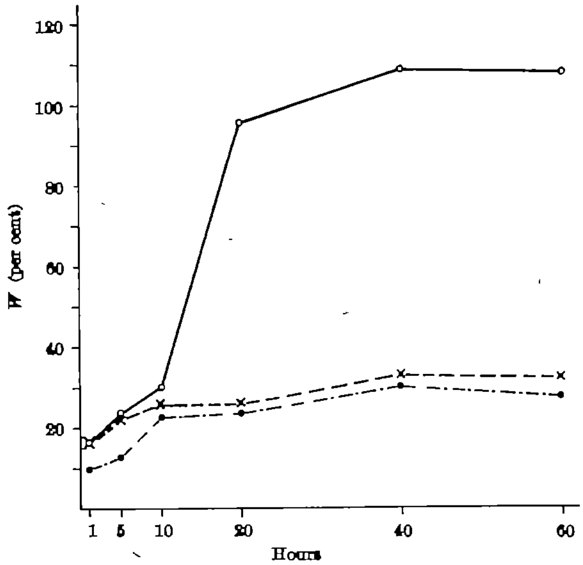

Fig. 2. Uptake of water in embryo (scutellum (○), aleuron layer (×) and starchy endosperm (●)) of Ramona wheat grains. Water content W as percentage of dry weight. Each point represents the average value of determinations in 36 sections

moisture and then checked on water content with the interference microscope or by weighing, respectively, a good proportionality between $\varphi_1-\varphi_2$ and m_w could be shown.

The accuracy of the method depends mainly on the accuracy in determination of the shift of the interference fringes, which in turn depends on the evenness of the sections. In good sections the fringes can be estimated to 0·1–0·2 fringes distance, corresponding to a water content of 1–2 per cent, nearly independent of the water content up to 30 per cent in the endosperm and 120 per cent in the germ. This fringe distance also determines the lower limit of detectable water.

In Fig. 2 the rate of uptake of water of different tissues in Ramona wheat grains is shown. The grains have been exposed to air saturated with water at 20° C. The water content is always highest in the germ (measured in the scutellum). Until about 10 h the water content in the aleuron layer is higher than in the starchy endosperm. After that time the water content of the aleuron and starchy parts approach the same asymptote. The distribution of water within this tissue is nearly equal throughout the whole grain.

Possible Relationship between Photosynthesis and the Rise in Respiration in Diseased Leaves

Several investigations, most recently reviewed by Millerd and Scott[1], have established that the respiratory rate is increased in the leaves of green plants after their infection with parasitic fungi. The pathway of this increased respiration is not definitely established, but experiments[2,3] have shown that the C_6/C_1 ratio is decreased in infected leaves, indicating that the hexose monophosphate shunt is enhanced. The inadequacies of the C_6/C_1 ratio for determining the magnitude of operation of the shunt have recently been stressed[4].

The cause of this increase in respiration is unknown. However, it was observed[5] that there was little or no increase in the respiration of etiolated barley leaves after their infection with *Erysiphe graminis* var. *hordei* (powdery mildew) although respiration increased as much as 300–400 per cent in infected green barley leaves. A possible explanation of this observation is that the increased respiratory rate is related to changes in photosynthesis.

Table 1. Rates of Photosynthesis in Leaf Segments, Chlorophyll Content and Activities of Aldolase and NADPH-diaphorase in Homogenates of Non-infected and Infected Green Leaves of Barley 144 h after Inoculation with *E. graminis* var. *hordei*

Tissue	Photosynthesis (μl. O_2 evolved/100 mg fresh weight/h)	Chlorophyll content (mg chlorophyll/g fresh weight)	Enzymatic activities (μmoles substrate utilized/min/g fresh weight)	
			Aldolase	NADPH-diaphorase
Non-infected	1,092	1·96	5·00	4·0
Infected	480	0·72	0·96	2·5

To determine whether the rate of photosynthesis as well as the rate of respiration changes in infected green leaves, the rates of both these processes were measured in infected and non-infected leaves of a barley variety highly susceptible to *E. graminis* var. *hordei*. At the same time, the activities of various enzymes catalysing both photosynthetic and respiratory reactions were compared in homogenates of green leaves. Further, the activities of various respiratory enzymes were measured in homogenates of infected and non-infected etiolated barley leaves.

Seeds of barley, variety Manchuria, highly susceptible to infection by *E. graminis* var. *hordei* were sown in pots of soil in a controlled growth room. The temperature was 70 ± 2° F. The green plants were illuminated with 20,000 lux of white light for 16 h/day. Five days after sowing when the first leaf was about 2 in. high some of the plants were inoculated with spores of *E. graminis* var. *hordei*[6]. At various times thereafter both inoculated and non-inoculated leaves were harvested for determination of photosynthetic and respiratory rates and enzymatic activities. Photosynthesis by leaf segments was determined manometrically by measuring oxygen production during illumination at 25° C. The concentration of carbon dioxide was maintained at 1 per cent by the use of a 'carbon dioxide-buffer'[7]. Respiratory rates of leaf segments were determined manometrically by measuring oxygen consumption in the dark. Leaf extracts for enzymatic assays were prepared as described elsewhere[8]. The following enzymes were assayed in extracts of barley leaves by continuously recording the progress of the reaction using a Cary spectrophotometer, isocitrate dehydrogenase, glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, enolase, aldolase, NADPH-diaphorase, NADH-cytochrome c reductase.

Measurements of photosynthetic rates, chlorophyll contents, aldolase and NADPH-diaphorase activities in non-infected and infected barley leaves 144 h after inoculation are given in Table 1. At this time not only is the over-all rate of photosynthesis in infected leaf segments decreased when compared with non-infected leaves, but also the chlorophyll content, and the activities of aldolase and NADPH-diaphorase. In photosynthetic cells most of the aldolase and NADPH-diaphorase activities are localized in the chloroplasts[9,10]. These observations show that there is a destruction of the chloroplast in infected leaves.

Table 2 gives results obtained for the rates of respiration and the activities of various respiratory enzymes of green barley leaves 144 h after inoculation. In the infected leaves the respiratory rate is about three times higher than in non-infected leaves. The activities of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase are considerably higher in homogenates of

Table 2. Rates of Respiration in Leaf Segments, and Enzymatic Activities in Homogenates of Non-infected and Infected Green Leaves of Barley 144 h after Inoculation with *E. graminis* var. *hordei*

Infected	73	1·00	0·42	0·87	1·01	0·51

Table 3. Rates of Respiration in Leaf Segments, and Enzymatic Activities in Homogenates of Non-infected and Infected Etiolated Barley Leaves 144 h after Inoculation with *E. graminis* var. *hordei*

Tissue	Respiration (μl. O_2 consumed/100 mg fresh weight/h)	Enzymatic activities in leaf homogenates (μmoles substrate utilized/min/g fresh weight)					
		Glucose-6-phosphate dehydrogenase	6-phosphogluconate dehydrogenase	Aldolase	Enolase	Isocitrate dehydrogenase	NADH-cytochrome c reductase
Non-infected	12	0·290	0·21	1·68	0·69	0·31	0·021
Infected	14	0·270	0·18	1·36	0·65	0·30	0·027

infected leaves compared with non-infected ones. On the other hand, there is no change in enolase, isocitrate dehydrogenase and NADH-cytochrome *c* reductase activities in the infected leaves. These findings indicate that the increased respiration in these diseased leaves is mediated through the hexose monophosphate shunt, rather than through the Krebs cycle. Time-course experiments disclosed that the onset of these respiratory changes coincided with the decrease in photosynthetic activity.

The results with green leaves may be contrasted with those obtained with barley leaves which were kept in continuous darkness to suppress the development of a photosynthetic system. Although the growth of the infecting fungus on these leaves appears to be normal, the infected leaves do not show a significant rise in respiration nor an increase in the activities of enzymes of the hexose monophosphate shunt when compared with non-infected leaves (Table 3).

These experiments are consistent with the hypothesis that the hexose monophosphate shunt plays a major part in mediating the increased respiratory rate of green barley leaves infected with *E. graminis* var. *hordei*. The fact that this increase in respiration is evident only when photosynthesis is decreasing, coupled with the observation that respiration is not increased in infected etiolated leaves, suggests that in this highly susceptible variety the decrease in photosynthesis and respiratory rise are related. Since both photosynthesis and the hexose monophosphate shunt are major metabolic sources of NADPH, one possibility is that the increase in respiratory activity is tied to a loss of capacity to photoreduce NADP+.

This work was carried out under the auspices of the U.S. Atomic Energy Commission. We thank Dr. J. Moseman, U.S. Department of Agriculture, Beltsville, Md., for supplying the barley seeds and *E. graminis*.

Concentration of Carbon Dioxide inside Leaves

DURING photosynthesis, the concentration of carbon dioxide in the intercellular spaces of a leaf, $[CO_2]_{int}$, determines the flux of carbon dioxide into the leaf if stomatal apertures and external concentration remain constant. Previously $[CO_2]_{int}$ has not been estimated during photosynthesis but has been equated with the external concentration at which photosynthesis ceased. Our object was to estimate $[CO_2]_{int}$ during active photosynthesis. Gabrielsen[1] found the minimum to which many plants would reduce the concentration of carbon dioxide in a closed system to be 100 p.p.m. by volume and concluded that $[CO_2]_{int}$ was also 100 p.p.m. Heath[2] arrived at the same conclusion. He drew air through leaves with porometers, varied the flow-rate and carbon dioxide concentration in the incoming air, and measured the carbon dioxide in the air leaving the leaf. Regardless of the rate of flow of air or concentration of carbon dioxide, the exhausted air contained about 100 p.p.m. carbon dioxide. Similar results were obtained by passing air over leaves at slow flow-rates.

The minimum concentration of carbon dioxide in a closed system or in a porometer system as used by Heath gives the concentration inside the leaf only when there is no net photosynthesis. This seldom occurs in normal outdoor conditions.

Carbon dioxide moves from the atmosphere to the surface of cells inside the leaf by turbulent transfer and diffusion to the leaf surface and by diffusion alone through the stomata and substomatal cavities to the internal cell surface. The process can be described by the equation:

$$P = \frac{[CO_2]_e - [CO_2]_{int}}{r_{a,CO_2} + r_{s,CO_2}} \qquad (1)$$

where P is the net photosynthesis or uptake of carbon dioxide, $[CO_2]_e$ and $[CO_2]_{int}$ are the concentrations of carbon dioxide (g/cm^3) in the external air and at the internal cell surface, r_{a,CO_2} is the resistance of external air, and r_{s,CO_2} is the resistance of the stomata and internal air to flow of carbon dioxide. We emphasize that $[CO_2]_{int}$ is at the surface of the cells inside the leaves, not at the site of carbon dioxide utilization.

Water is transpired from cell surfaces inside the leaf and escapes along the same path which carbon dioxide travels as it enters. Transpiration can be described by a similar equation:

$$T = \frac{[H_2O]_{int} - [H_2O]_e}{r_{a,H_2O} + r_{s,H_2O}} \qquad (2)$$

where T is transpiration, $[H_2O]_{int}$ and $[H_2O]_e$ are concentrations of water vapour (g/cm^3) in the air at the internal cell surface and in the external atmosphere, and r_{a,H_2O} and r_{s,H_2O} are the resistances of air and stomata to water vapour movement. Gaastra[3] found the ratio of $\frac{r_{a,CO_2}}{r_{a,H_2O}}$ in a system that included turbulent air to be about the same as $\frac{D_{H_2O}}{D_{CO_2}}$, the ratio of the diffusion coefficients for water and carbon dioxide in air. Since the diffusion path-lengths through the stomata are identical for water and carbon dioxide it can be shown that $\frac{r_{a,CO_2} + r_{s,CO_2}}{r_{a,H_2O} + r_{s,H_2O}}$ also equals $\frac{D_{H_2O}}{D_{CO_2}}$. Therefore, solving equations 1 and 2 simultaneously for $[CO_2]_{int}$ yields:

$$[CO_2]_{int} = [CO_2]_e - \left(\frac{P}{T}\right)\left(\frac{D_{H_2O}}{D_{CO_2}}\right)([H_2O]_{int} - [H_2O]_e) \qquad (3)$$

The right-hand terms of equation 3 were measured with corn plants actively assimilating carbon dioxide. Thus we could estimate $[CO_2]_{int}$ during active photosynthesis. The plants were in a 40 cm × 40 cm × 50 cm transparent chamber. This chamber was illuminated by seven 300-W incandescent spot lamps, partially immersed in water to remove sensible heat and infra-red radiation. The $[CO_2]_e$ was measured by means of an infra-red gas analyser coupled with an adjustable range, adjustable zero recording potentiometer. Whenever $[CO_2]_e$ fell to a pre-set level, measured quantities of carbon dioxide were automatically metered into the chamber to maintain the desired concentration ± 10 p.p.m. The meter values gave P. The $[H_2O]_e$ was measured by means of an electrical hygrometer and controlled at $6 \cdot 2 \times 10^{-6}$ g/cm^3 within $\pm 0 \cdot 1 \times 10^{-6}$ g/cm^3 by condensing water on a cold coil. The condensed water was measured and gave T. The temperature of the leaf was measured by means of a small thermocouple inserted in the leaf and a temperature of 20° ± 0·1° C was controlled indirectly by heating the

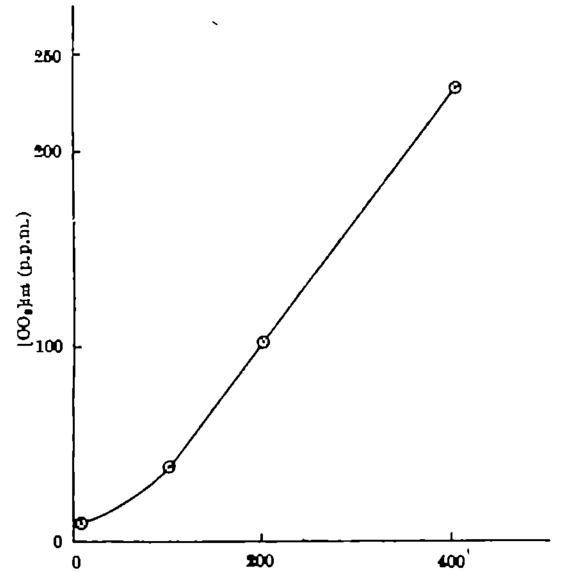

Fig. 1. Concentration of carbon dioxide at the internal cell surface, $[CO_2]_{int}$, as a function of the concentration in the atmosphere, $[CO_2]_a$

air. The $[H_2O]_{int}$ was assumed equal to the saturation vapour concentration at leaf temperature[3].

The illumination on a horizontal plane was 10,000 ft.-candles at the top and 6,500 ft.-candles at the bottom of the corn shoots. The concentration of carbon dioxide in the atmosphere, $[CO_2]_a$, was maintained at 8, 100, 200 and 400 p.p.m. and T and P were measured at each concentration. $[CO_2]_{int}$ was calculated and is shown in Fig. 1. Each point in Fig. 1 was calculated from the average of six consecutive 10-min determinations of T and P after a steady-state was reached.

As expected, the concentration of carbon dioxide inside the leaf increased as the concentration in the atmosphere increased. However, the increase in $[CO_2]_{int}$ was not directly proportional with increasing $[CO_2]_a$ because stomatal resistance changed with changes in carbon dioxide concentration. Measurements of the stomatal apertures were taken by means of silicone rubber replicas[4]. At 8 p.p.m., 100 per cent of the stomata had an aperture-width greater than 1μ. At 100 p.p.m., 70 per cent; at 200 p.p.m., 26 per cent; and at 400 p.p.m., only 12 per cent had apertures that large. In Fig. 1, $[CO_2]_{int}$ varied from 8 to 240 p.p.m. as $[CO_2]_a$ changed from 8 to 400 p.p.m.

Thus the concentration of carbon dioxide inside leaves is determined by the concentration difference and a series of resistances in the pathway from the atmosphere to the point of enzymatic fixation. Since both concentrations and resistances at different points in the pathway change, it is unrealistic to speak of a single concentration of carbon dioxide inside a leaf during photosynthesis, except under carefully specified conditions. In a steady-state, however, the concentration at the internal cell surfaces can be determined experimentally by a simultaneous measurement of photosynthesis and transpiration; or in the special case, when photosynthesis ceases because of low concentration of carbon dioxide, the concentration inside and outside the leaf will be the same.

Niacin Content of Coffee

In a recent communication[1] A. Carvalho quoted some results of determinations of niacin in samples of coffee beans, which indicated variations in niacin content according to whether the coffee was grown with or without shade, and according to whether the 'cherries' were sun-dried or de-pulped before drying.

These results, which vary from 0·160 to 0·400 mg/g, are of the same order as the previously published values for roasted coffee[2-5], and Carvalho has since informed me that they were in fact made after the samples had been roasted in a small electric roaster, to an intensity a little less than that of a type called Italian roast (namely, a high roast). Due to an omission this point was not made clear in his letter.

The production of nicotinic acid (namely, niacin) by the decomposition of trigonelline during the roasting of coffee has been demonstrated[3], the nicotinic acid content thereby increasing to up to 10 times the amount present in the raw beans. The effects of roasting conditions on niacin content of roasted coffee therefore far outweigh variations in niacin content of the raw beans, and the trigonelline content of the raw beans appears to be a deciding factor. It would therefore be interesting to know of the effects of growing and processing conditions on the trigonelline content of coffee beans.

Similar considerations might also apply to the production of pyridine (one of the constituents of coffee aroma), which also is formed by the decomposition of trigonelline during roasting[6]. The effects of growing and processing conditions on trigonelline content would be expected to have a bearing on flavour differences in roasted coffee.

Fluorescent Lighting in Biological Research

In view of the prevalent use of fluorescent lighting in many types of biological research (for example, refs. 1 and 2), it is felt that the following observations may be of general interest.

Fluorescent tubes contain mercury vapour; the short-wave-length discharge induces a visible radiation from the phosphor coating of the tube walls. During research on another topic[3], we observed emission from a typical daylight tube at 313, 334 and 366 mμ as well as in the visible spectrum. It was further shown that the glass of these tubes, 1 mm in thickness, transmitted over 50 per cent of the incident radiation at 310 mμ.

It has been shown that ultra-violet of 313 mμ is mutagenic in *Drosophila*[4] and it is generally known that light of this wave-length causes damage to tissue: while the ultra-violet incident on a surface more than 1 m from a 40-W tube is far less than that from summer noon sunlight, it is worth noting that it is common to place the fluorescent tube inside the cage or incubator and to leave it running continuously. This may seriously affect experimental results.

Most of the tubes also radiate strongly at 405 and 436 mμ and while this radiation may not be dangerous to living material, it may accelerate degradation and bleaching of various of the more labile animal pigments; this may be of significance when it is considered that the radiation from most types of daylight fluorescent tubes is at least five times and may be over ten times that from a 100 W tungsten lamp at 400 mμ for the same radiation at 540 mμ. Museum curators may find this to be of interest.

MICROBIOLOGY

Bacterial Growth at Low Population Densities (II)

In a previous communication[1], the possible influence of low population densities on the growth of *Spirillum serpens* under steady-state conditions (lactate growth limiting) was reported. Qualitative evidence was given by the fact that the inhibition of growth at low concentrations of the limiting nutrient entering the chemostat was partly removed by lowering the concentration of dissolved O_2 or the addition of ascorbic acid to the medium. It was suggested that the reducing power of the cells becomes growth limiting in the system when the population density falls below a certain value. Additional data have been collected to substantiate this suggestion.

During the steady-state, the population density (x) is a function of the concentration of the limiting nutrient entering the chemostat (s_r): $x = y\,(s_r - s)$, where y is the yield coefficient and s the concentration of the limiting nutrient in the chemostat[2]. After direct determination of x (ref. 2) and s (with DPN and lactate dehydrogenase[3]), the decrease of growth observed in the presence of a decreasing s_r was calculated at the expense of the yield coefficient: $y = \frac{x}{s_r - s}$. The maximum growth rate (μ_{max}) and the saturation constant (K_s) were the same as given in ref. 2. The dilution rate (D) was 0·5 μ_{max}.

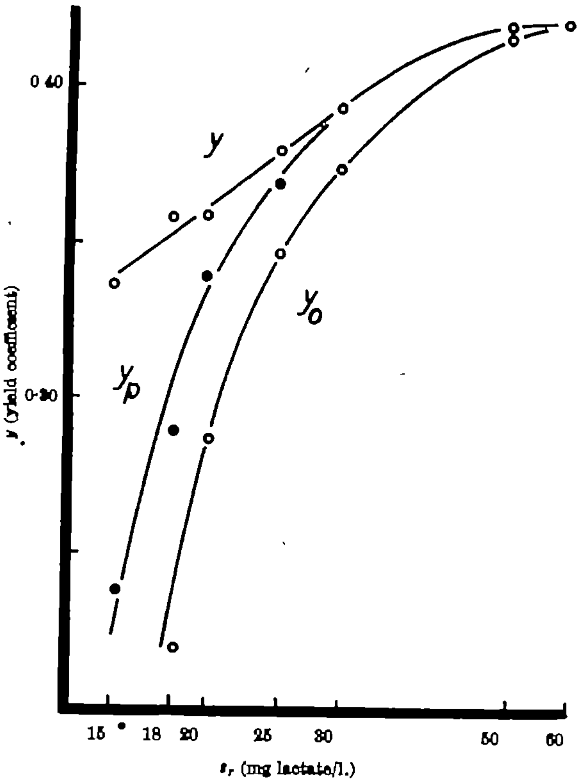

Fig. 1. Yield coefficient (y, y_o, y_p) plotted against the concentration of the growth-limiting nutrient entering a steady-state culture (chemostat) of *Spirillum serpens*

In Fig. 1, y_0 has been calculated on assumption that s stays constant at the given dilution rate ($s = 2{\cdot}2$ mg lactate/l.). Direct determination, however, showed a definite increase of s when s_r was decreasing below 50 mg lactate/l. This apparent waste of the limiting nutrient suggests an inhibiting effect upon the uptake and invalidates the definition of $s = K_s \frac{D}{\mu_{max} - D}$ (ref. 1) at low values of s_r in the present case. If the actual data of s are used in the calculation, y shows a slower decline as compared with y_0 (Fig. 1).

Repeating the experiment after the addition of 0·002 per cent ascorbic acid to the medium flowing into the chemostat, s was observed to increase more slowly. In other words, by supplying a reducing agent, the apparent waste of the limiting nutrient was partly prevented. Calculation of the yield coefficient in this case (y_p in Fig 1) gave a line almost parallel to y_0. Lowering the concentration of oxygen in the aerating gas mixture had a similar effect.

That part of the growth-inhibiting effect which is attributed to a decreasing reduction power of the population at low densities does not occur before s_r decreased below 30 mg lactate/l. The difference between the curves of y_0 and y_p demonstrates the remaining part of the growth-inhibiting effect which is not explained by a population phenomenon. In general, sub-optimal growth conditions result in a decrease of the yield coefficient at low population densities due to bacterial action on the environment. This effect is independent of a yield-affecting endogenous respiration or maintenance metabolism.

Lysogeny in *Alcaligenes faecalis* and the Host-range of *A. faecalis* Bacteriophages

Eighty-six strains of *Alcaligenes faecalis* were investigated. Five of these were N.C.T.C. cultures. The remaining strains were isolated from faeces and correspond to the description in Bergey's *Manual of Determinative Bacteriology*[1]. Media adopted were those previously[2] used. Lysogeny was investigated by growing organisms singly and in mixtures in broth for 10 days and by ultra-violet induction. These methods have been described[2]. Thirty of the organisms proved lysogenic for one or more of the 86 strains. Thirteen strains were inducible by ultra-violet light. Moore and Pickett[3] investigated 40 strains of *A. faecalis*-like organisms and found 3 of them to be lysogenic for other members of the group.

Attempts were made to isolate phages active on *A. faecalis* from sewage by the enrichment technique of Adams[4]. Twenty-three phages were isolated in this manner. Phages were purified by repeated single plaque isolations. Lysates were stable when stored above 0·1 vol. of chloroform.

The host ranges of the 53 phages were investigated by spotting drops of lysates (plaque-forming titres about 10^8/ml.) on freshly poured lawns of the 86 strains of

A. faecalis and 110 Providence and *Proteus* cultures previously[5] used. A large number of *Escherichia coli* and *Pseudomonas aeruginosa* as well as *Shigella* and *Salmonella* spp. were also used in these experiments. Apart from their action on *A. faecalis* which enabled all 53 phages to be differentiated from one another, 5 of these phages productively lysed one or more of 4 *Proteus vulgaris* strains, 14 *P. mirabilis*, 2 *P. rettgeri* and 6 *Providence* strains. Two of these 5 phages were isolated from lysogenic strains of *A. faecalis* and lyse *P. rettgeri* N.C.T.C. 7480 and 7481 and *Providence* strain N.C.T.C. 9269. The remaining 3 phages (isolated from sewage) each lyse at least one strain each of *P. rettgeri*, *P. vulgaris*, *P. mirabilis* and *Providence*.

Organisms able to support the growth of a particular bacteriophage are considered[4] to be closely related and these results support previous findings[6] of relatedness between members of the *Proteus* group and between the latter and *Providence* organisms. With certain *Pasteurella pestis* phages[7] these 5 *A. faecalis* phages share the distinction of being able to attack members of two families.

This work was aided by grants to one of us (J. N. C.) from the South African Council for Scientific and Industrial Research.

Interspecific Recombination in *Streptomyces*

GENETIC recombination of Streptomycetes was first reported by Sermonti and Spada-Sermonti in 1955[1]. By crossing different nutritional mutants of *Streptomyces coelicolor* various auxotrophic and prototrophic types have been obtained.

Several authors have obtained true recombination by crossing different mutant strains of *S. coelicolor*[2]. Moreover, recombination of different nutritional mutants of the same species have been reported for *S. rimosus*[3], *S. fradiae*[4], and *S. griseoflavus*[5].

In this work recombination experiments have been carried out with mutants of the following species of *Streptomyces*: *S. rimosus* A.T.C.C. 10910, *S. aureofaciens* A.T.C.C. 10762 and *S. coelicolor* I.S.S.

Nutritional mutants of *S. rimosus* and *S. aureofaciens* were obtained by ultra-violet radiation using the replica plating technique. Mutants of *S. coelicolor* were kindly supplied by Prof. G. Sermonti, Istituto Superiore di Sanità, Rome. Nutritional mutants were used because of their stability and suitability for recombination.

Two parental strains have been inoculated together on slants of complete medium, and incubated four days at 30° C. Collected conidia were suspended in sterile water, filtered through a cotton filter in order to remove hyphal fragments and clusters of conidia, and seeded on selective media.

The number of recombinant colonies recovered in various experiments is reported in Table 1.

Recombination has been obtained in all the interspecific crosses examined, namely, *S. rimosus* × *S. coelicolor*, *S. rimosus* × *S. aureofaciens* and *S. aureofaciens* × *S. coelicolor*. Recombination rates ranged from about 10^{-6} to 10^{-4} according to the various strains used and the selective plating media.

Considerable changes in pigmentations of recombinants were observed in the progeny of crosses *S. rimosus* × *S. coelicolor*, ranging from cream-white colour (*S. rimosus*) through grey, pink and red, to strong blue pigment (*S. coelicolor*), more intense than the normal colour of this species.

Table 1. INTERSPECIFIC RECOMBINATION IN *Streptomyces*

Crosses	No. of spores plated per dish	Supplements to minimal medium	No. of recombinants recovered*
S. rimosus × *S. coelicolor*			
*M*1 arg × *M*10 his	12×10^6	—	(12)
		HIS, STR	(17)
*M*1 arg × *M*15 arg	4×10^6	—	9 (45)
*M*1 arg × *M*16 arg	5×10^6	—	7 (80)
*M*3 nic × *M*13 met phe str	2×10^6	—	(5)
		MET	(6)
*M*8 arg his × *M*13 met phe str	5×10^6	—	20
		HIS	21
		HIS, PHE	24
		ARG	528
		ARG, MET	532
*M*8 arg × *M*17 met arg ade	$4{\cdot}5 \times 10^6$	—	1 (114)
		MET, ARG	1 (128)
		HIS, ADE	2 (140)
S. rimosus × *S. aureofaciens*			
*M*4 his × *M*6 met	5×10^6	—	0
*M*9 his × *M*6 met	$2{\cdot}5 \times 10^6$	—	6
S. aureofaciens × *S. coelicolor*			
*M*5 his × *M*10 his	$4{\cdot}5 \times 10^6$	—	0
*M*5 his × *M*13 met phe str	1×10^6	—	20
		PHE	24
		MET	28

ARG, arginine; HIS, histidine; ADE, adenine; PHE, phenylalanine; MET, methionine; NIC, nicotinic acid; STR, streptomycin. The same symbols in small letters indicate mutant alleles for requirement of the growth factor, or for resistance to the drug (str).

* Mean values from 10 consecutive assays, each on 10 plates. The numbers in parentheses are small colonies.

Arginineless recombinants were isolated from the combination *S. rimosus* *M*8 arg his × *S. coelicolor* *M*13 met phe str. Prototrophic recombinants were obtained from one of three isolated strains crossed with parent *M*13.

The relevance of the interspecific crosses in *Streptomyces* from the taxonomic, as well as from the biochemical point of view, needs no emphasis.

This work was supported by 'PLIVA' Pharmaceutical and Chemical Works, Zagreb.

A Medium for the Isolation of *Streptococcus faecalis, sensu strictu*

DURING the course of an ecological survey of the fæcal streptococci, the need has arisen for a medium which is more highly selective for *Streptococcus faecalis* than media devised for the enumeration of enterococci in general. A number of workers[1–4] have indicated that *Strep. faecalis* is the predominant streptococcus (Lancefield group *D*) of the gut of man, and that this species is relatively rare in the gut of animals. Hence a specific means of demonstrating this organism would be of some value to sanitarians as a means of assessing human fæcal pollution, at least in certain climatic regions[5].

Slanetz and Bartley have recommended an agar medium which is capable of recovering larger numbers of types of enterococci than media formerly used, and the efficiency of this medium is under investigation. It is claimed[6] that strains of *Strep. faecalis* may be distinguished from other enterococci, when grown on Slanetz and Bartley's medium, by the reduction of 2,3,5-triphenyl tetrazolium chloride (TTC) to the formazan, thus producing dark maroon colonies. Barnes[7] has shown that the reduction of TTC is reliable, however, only at pH 6·0–6·2 and not at pH 7·2 as in Slanetz and Bartley's medium.

In the present work, 201 strains of enterococci, isolated on Slanetz and Bartley's medium from sewage effluent and river water, were classified biochemically by conventional methods. More than a quarter of the 201 strains produced dark maroon colonies; but 41 per cent of this fraction were not 'typical' *Strep. faecalis*, as expected, but unidentifiable intermediate strains. Conversely, a number of colonies which were not maroon in colour were identified as *Strep. faecalis*. It appears, therefore, that a reliable quantitative determination of this organism cannot be obtained with this medium.

Central to the problem is the exclusion of the numerous intermediate types which apparently are not of critical significance in demonstrating human faecal pollution. An attempt has been made to formulate a medium which will considerably reduce the number of 'intermediates' and facilitate the recognition of *Strep. faecalis, sensu stricto*.

It was decided that the only satisfactory medium would be one that would select strains possessing several characteristics of the organism, and not merely the one factor of TTC reduction. An agar medium incorporating four characteristics was devised, as follows:

(1) *Ability to grow at 45° C following 4 h resuscitation at 37° C.* This technique has been successfully used by Burman[8] with Slanetz and Bartley's medium to eliminate many of the atypical strains encountered in water.

(2) *Ability to ferment sorbitol.* Kjellander[9] has shown that this characteristic is also apparent in a large number of human-derived enterococci, but is encountered more rarely in animal-derived strains.

(3) *Ability to decompose tyrosine.* This is another characteristic of the species, particularly of human strains, but in the medium described here the test is performed in a different manner from that originally devised by Sharpe[10].

(4) *Reduction of TTC at pH 6·2.* See above.

The medium has the following composition: peptone (Evans) 10 g; 'Yeastrel' 1 g; sorbitol 2 g; tyrosine 5 g; Oxoid agar 12 g. These constituents are dissolved in 1 litre of distilled water and autoclaved at 10 lb. for 10 min. The pH of the medium is then adjusted to 6·2 and 0·01 per cent TTC and 1 per cent thallous acetate added. An additional 4 g of tyrosine are also added while still hot to provide a suspension, so that decomposition of tyrosine by a colony will result in the formation of a clear zone surrounding it. It is important to note that autoclaving is required to dissolve some of the tyrosine completely, while the remainder forms the suspension. No other sterilization is necessary. Plates are poured when the temperature of the medium is near the setting point so that a uniform suspension of the undissolved tyrosine is obtained. A shallow layer of the medium without added tyrosine is poured first and allowed to set. This is followed by a layer of medium with the added tyrosine. The period of incubation is three days at 45° C after 4 h at 37° C. Only uniformly dark maroon colonies, encircled by clear zones, are regarded as 'typical' (Fig. 1). The medium as devised may be used in conjunction with membrane filters, though in this instance the membrane is placed face downwards on the surface of the agar after filtration.

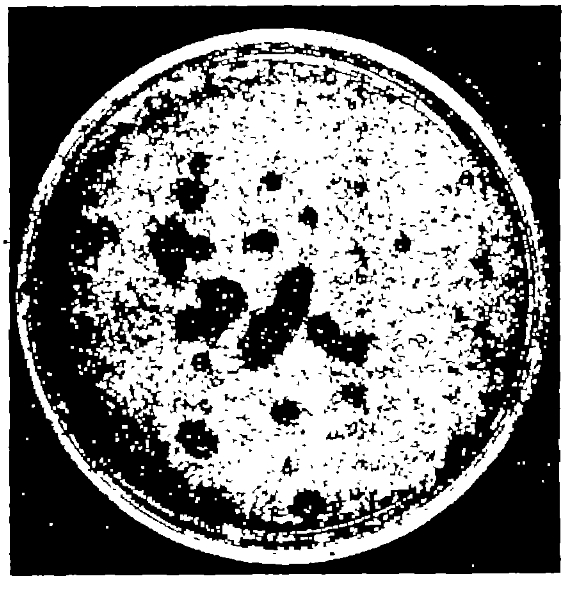

Fig. 1. A pure culture of *Strep. faecalis* on sorbitol/tyrosine/TTC medium. The zones of clearing appear as dark areas

The medium has been used successfully for the primary isolation of *Strep. faecalis* both from faeces and from water. Particular attention has been paid to strains of enterococci other than *Strep. faecalis* which may give a false 'positive' result when grown on this medium. Of the 201 strains of enterococci isolated on Slanetz and Bartley's medium, 26 strains which fermented sorbitol were not identifiable as *Strep. faecalis*. From these 26 strains, only three also produced dark maroon colonies, of which two did not attack tyrosine. Hence the proportion of false positives obtainable by the method described here, using the sorbitol/tyrosine/TTC medium, can be expected to be relatively low. An analysis of the faeces of eight animal species by direct plating on this medium revealed only two strains which gave false positive results.

GENETICS

Multiple Allelic Control of Chlorophyll *b* Level in *Arabidopsis thaliana*

IN maize, the plant best known genetically, there are no viable chlorophyll *b* deficient mutants[1,2]. Röbbelen[3] described an *Arabidopsis* mutant devoid of this pigment which was, however, a lethal one. It has been reported that in barley only chlorophyll *a* is necessary for viability[4]. Among algae viable chlorophyll *b*-less mutants are not infrequent[5]. Since chlorophyll *b* is a normal constituent of the photosynthetic apparatus of all angiosperms and its precise role is little understood, viable mutants involved in the development of this pigment are of interest.

In our X-radiation experiments we obtained a few yellow-green mutants with reduced amount of chlorophyll *b*. Genetic tests have shown these to comprise a series of alleles. The locus (*ch*) has been assigned to our fourth linkage group with the following gene sequence: *gi, xv, P, ch, pa*. These *ch* mutants show fairly normal fertility and Mendelian inheritance. Detection of the chlorophyll *b* deficiency is easy. Good ascending paper-chromatograms can be developed (solvent: 10 vol.

petrol ether–1 vol. acetone) in 15–20 min at 5° C (Fig. 1) even from tissues weighing only a few milligrams.

Two of the alleles are of special interest: ch^1, which does not allow the production of any detectable amount (paper-chromatography, sugar-column chromatography, spectrophotometry) of chlorophyll *b*, and ch^2, which determines a reduced amount of this pigment. The phenotype of the mutants can be characterized by growth and pigment-content data (Tables 1 and 2). The size of the yellow-green plants is considerably reduced in comparison to that of the wild-type, but there is no difficulty in growing the mutants under the usual culture conditions. The appearance of these mutants (except for colour) is quite normal (Fig. 2).

When light intensity is reduced, the pigment content increases (on tissue weight basis), but still there is no chlorophyll *b* in ch^1. The percentage increase of the latter pigment in ch^2 is comparable with that in the wild-type. Apparently the reduction of the amount of chlorophyll *b* in *Arabidopsis* is not due to light destruction as observed in algal mutants by Allen[5].

Attempts to restore the normal chlorophyll *b* level by feeding the mutants on an aseptic agar medium supplemented with a variety of substances were unsuccessful. On irradiation or treatment with chemical mutagens of plants heterozygous for the locus, numerous *ch* sectors appear. These could be due to deletion of the critical segment of the wild chromosome, to mutation at the locus, or to non-disjunction. The margin of the genetically different tissues is clearly demarcated, showing that the immediate precursor cannot diffuse from the wild-type sector to the mutant.

Fig. 1 Contact print of a paper chromatogram of ch^1, ch^2 mutants and wild-type; *a*, chlorophyll *a*; *b*, chlorophyll *b*

Fig. 2. Phenotype of wild-type and mutants

Table 1. Some quantitative characteristics of wild-type and two *ch* mutants grown in the greenhouse, exposed to sunlight during the day and illuminated with 200-watt incandescent bulbs during the night. Temperature, 20°–25° C. Light intensity, 400–500 ft.-candles.

	Fresh weight (mg)	Dry weight (mg)	Length of stem (cm)	No. of buds, flowers and fruits
Wild	314·00	30·56	23·70	59·10
ch^2	60·13	7·13	10·19	18·80
ch^1	25·65	2·96	6·25	10·00

Table 2. Pigment content of wild-type and two *ch* mutants grown under two different light intensities (pigment γ/fresh weight g analysed by the technique of Röbbelen (ref. 3))

	Total pigment 1	Chlorophyll *a* 3	Chlorophyll *b* 4	Carotenoids 5	Ratios 3 : 4	Ratios (3 + 4) : 5
Strong light*						
Wild	1,184	736	255	193	2·9	5·1
ch^2	748	560	67	121	8·6	5·2
ch^1	508	416	0	92		4·5
Weak light†						
Wild	1,553	986	311	256	3·2	5·1
ch^2	1,058	815	93	150	8·8	6·1
ch^1	811	712	−13‡	99		7·1

* Culture conditions identical with that indicated in Table 1.
† Cultured in a cold room at 20° C and 400 ft.-candles illumination for 8 h/day.
‡ Negative value is due to technical error.

Chlorophyll *a* does not seem to be an immediate precursor of chlorophyll *b* as has been considered possible[6,7], since no accumulation of the former occurs in the mutant. Rather a decrease of chlorophyll *a* is found, which may be an indication of their common origin.

By means of lugol tests it was found that the absence of chlorophyll *b* has no important bearing on starch synthesis in these mutants. Thus Seybold's early suggestion and some other circumstantial evidence (cf. ref. 8) as to the role of this pigment are not applicable here in spite of the fact that some supporting data have been obtained with another *Arabidopsis* mutant[3].

It is possible that chlorophyll *b* has some stabilizing effect on the pigment system such as Allen[5] proposed, since all *ch* mutants are lower in the total amount of pigments.

Our preliminary experiments with intact plants appear to support the suggestion of Arnon *et al.*[9] that chlorophyll *b* is involved in photo-oxidation.

We thank Drs. G. Y. Kikudome, E. R. Sears and Lotti M. Steinitz-Sears for comments and corrections in the manuscript.

CYTOLOGY

Meiosis in the Male *Periplaneta americana*

CYTOLOGY of the common cockroach *Periplaneta americana* (Blattidae) dates back to 1909[1], and yet recent re-examination has not only brought to light interesting details, but also much controversy[2–4]. It was therefore felt necessary to examine the locally available species of cockroaches with the view of understanding the intricacies of the problem. Absence of diplotene-diakinesis and chiasmata in meiosis in the male has been claimed and various explanations have been marshalled[1,9,10]. But Lewis and John[7,8], taking into consideration all the aspects of indirect evidence, state that chiasmata might occur at the terminal ends of chromosomes and might terminalize rapidly.

Our observations on *Periplaneta americana* collected in and around Mysore City show that at the stage at which prometaphase stretch is operating, we come across open-cross bivalents (Figs. 1, 8, 10), ring-bivalents (Figs. 2, 3, 6, 7), rod-bivalents (Figs. 6, 7, 10), rod-bivalents with two chiasmata in the long arm of the chromosome (Fig. 9) bivalents with sub-terminal association (Fig. 5), tetravalents in the shape of rings (Figs. 4, 6) and open-chains (Fig. 7). These clearly indicate that chiasmata do occur and obviously for a very brief period. The point of special interest here is that the stages Lewis and John[7,8] have seen in the material treated with colchicine are seen in our untreated populations.

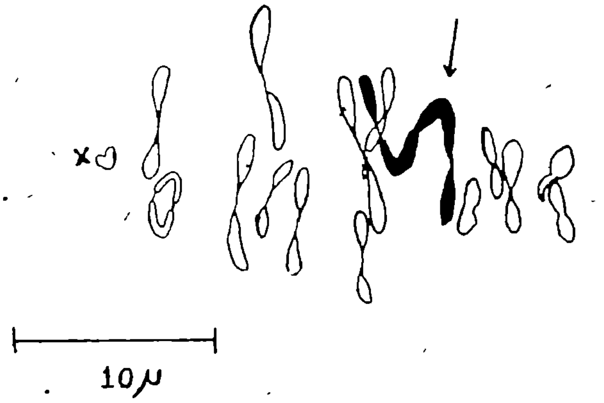
6

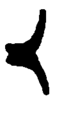
Fig. 6. Late prometaphase showing a ring-tetravalent with a zigzag orientation (indicated by arrow). *X* is located to one side of the spindle. Except one ring-bivalent, the rest are rod bivalents



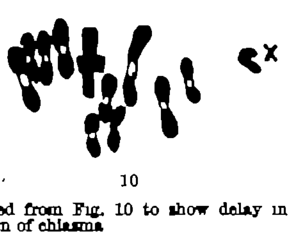
7

Fig. 7. Same as Fig. 6, except for a chain-tetravalent showing zigzag orientation

8



9



10

Fig. 8. Open-cross bivalent selected from Fig. 10 to show delay in terminalization of chiasma

Fig. 9. A bivalent from metaphase I showing two chiasmata in the long arm of the chromosome

Fig. 10. Metaphase I showing an open-cross bivalent. Only 11 bivalents are shown

As to the nature of chromosomes, an examination of the gonial metaphase chromosomes reveals that most of the chromosomes are sub-metacentric but a few are acrocentric (contrary to the observations of Sharma *et al.*[3]). The gonial metaphases show 33 chromosomes ($2n = 32A + X$). Of the 85 spermatogonial plates examined, 3 of them distinctly showed 34, the extra chromosome being the smallest of the complement which perhaps represents a supernumerary chromosome. This becomes clear from an examination of early gonial prophases which show two condensed bodies differing in size: the larger is *X* and the smaller is supernumerary chromosome. There is an appreciable condensation of chromosomes by the end of pachytene. Sharma *et al.*[2,3] do not believe in the progressive condensation of the bivalents, but believe in the abrupt condensation of bivalents at prometaphase. However, in this observation we concur with John and Lewis[4–6]. In metaphase I, the *X* chromosome seems to orient itself on one side of the spindle and always shows 'precession'; but in 2 out of 93 anaphase I stages examined, *X* showed lagging.

Negatively Stained Lipoprotein Membranes: the Validity of the Image

THE use of negative staining techniques in electron microscopy has recently been extended to the examination of lipoprotein membranes[1–3]. In view of present attempts to interpret data obtained by these techniques in terms of the molecular organization of the intact, hydrated membrane, attention must be directed to X-ray diffraction data which indicate that the dehydration of such lipoprotein systems generally leads to extensive reorganization of lipid and protein components. Freshly isolated preparations of red cell ghosts, mitochondria, and microsomes (unpublished results) do not give any low angle diffraction bands but the dried preparations all show a strong diffraction at about 60 Å, which is suggested to be characteristic of an independent lipid phase.

In the case of nerve myelin the detailed low-angle diffraction pattern from the fresh nerve is interpreted in terms of a single diffracting phase in which the fundamental repeating unit is the intact, hydrated lipoprotein layer, but studies of the effects of air drying[4–6] have revealed the formation of several independently diffracting phases in the dried specimen. These phases have been identified as a residual lipoprotein, cholesterol, and a residual mixed lipid. Although fixatives such as osmium tetroxide and potassium permanganate prevent the separation of independently diffracting units during drying, negative stains such as sodium phosphotungstate do not, and the unfixed, negatively stained lipoprotein preparation is undoubtedly a multi-phase system. This is confirmed by the low-angle diffraction pattern obtained from a saponin-treated preparation of myelin which has been mixed with 1 per cent sodium phosphotungstate at *p*H 7 and air dried. Electron micrographs of the same preparation revealed lamellar fragments which showed a hexagonal distribution of dense spots similar to that demonstrated in negatively stained preparations of saponin-treated red cell ghosts by Dourmashkin *et al.*[1].

Subsequent work[7,8] has shown that a very similar pattern can be obtained from a lecithin–cholesterol mixture or even from cholesterol alone when these have been allowed to interact with saponins. It therefore seems likely that the strikingly regular hexagonal pattern observed in negatively stained preparations of saponin-treated myelin or of saponin-treated red cells is due to a lipid phase, possibly pure cholesterol, which has separated from the lipoprotein structure during drying. This hexagonal phase may, in fact, be formed only during the final stages of dehydration, and the observed dimensions and form of the complexing between saponin and cholesterol may have little direct relevance to the structure of the intact membrane and its modification by saponin. A final assessment of the significance of these electron microscope observations will not be possible until the exact conditions necessary for the formation of this hexagonal phase in cholesterol-containing systems have been established. Meanwhile, it is essential that the electron microscopist who studies lipoprotein systems by negative staining techniques not involving the use of a fixative should be cautious in relating his observations to the intact lipoprotein membrane, for in all probability he is looking at several different 'breakdown products' of the original structure.

VIROLOGY

Inhibition of *Enterovirus* Ribonucleic Acid Synthesis by 2-(α-Hydroxybenzyl)-benzimidazole

2-(α-HYDROXYBENZYL)-BENZIMIDAZOLE (HBB) is a specific chemical inhibitor of enterovirus reproduction[1,2]. Examination of its mechanism of action has shown that it prevents the production of the infective viral RNA of susceptible viruses[3]. These studies left open the question whether HBB in fact inhibited the synthesis of viral ribopolynucleotide strands, or merely prevented viral RNA from becoming infective. A simple experimental approach to this question was offered by the finding that actinomycin *D* is a specific inhibitor of cellular RNA synthesis, but does not affect viral RNA synthesis[4].

The virus-cell system used consisted of Coxsackie *A*9 virus and primary monolayer cultures of rhesus monkey kidney cells[3]. A coverslip technique[5] was used, and RNA synthesis was measured by incorporation of tritiated uridine, as follows: at intervals, cells were exposed to 1·0 μc. of tritiated uridine (specific activity 6·74 c./m.mole) in the presence of 20 μg of thymidine[6]. Incorporation was stopped after 15 min by fixation of cells in cold acetic alcohol (3 parts ethyl alcohol and 1 part glacial acetic acid). After 2 extractions with 5 per cent perchloric acid at 4° C the samples were washed 5 times with water, once with alcohol-ether (equal parts) and twice with ether. The coverslips were dried at 70° C for at least 2 h, placed on aluminium planchets, and counted in a windowless gas-flow counter.

It was determined in preliminary experiments with varying concentrations of actinomycin *D* that 1 μg/ml. reduced uridine uptake by uninfected cells by 90 per cent in 3–5 h and by 95 per cent in 7–9 h. In investigations with virus-infected cells, treatment with this concentration of actinomycin was begun 2 h before virus inoculation. In a single infectious cycle, with virus collected 8 h after inoculation, actinomycin caused no measurable decrease in virus yield. HBB was used at a concentration of 219 μM. At this concentration, HBB completely inhibits the production of the infective RNA of Coxsackie *A*9 virus and also of infective virus particles, but it has no effect on the uptake of uridine into cellular RNA[3].

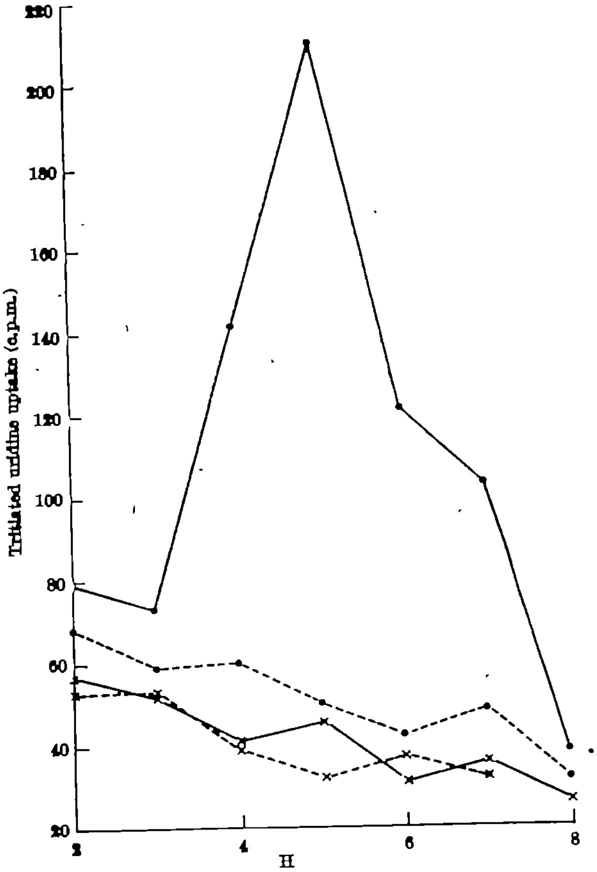

Fig. 1. Coxsackie *A*9 virus-induced stimulation of RNA synthesis in actinomycin-treated monkey kidney cells, and its inhibition by 219 μM 2-(α-hydroxybenzyl)-benzimidazole (HBB). ●—●, Infected; ●---●, uninfected; ×—×, infected + HBB; ×---×, uninfected + HBB

Fig. 1 shows the results of a typical experiment. In actinomycin-treated cells, infection with Coxsackie *A*9 virus induced a marked increase in the uptake of tritiated uridine into acid-insoluble form. The incorporated radioactivity could be removed by treatment of fixed cells with ribonuclease. The virus-induced RNA synthesis was first observed 4 h after inoculation, with a peak at 5 h; it then decreased, and was no longer detectable at 8 h. As can be seen in Fig. 1, 219 μM HBB completely prevented the virus-induced incorporation of tritiated uridine into RNA.

It is possible that not all the RNA synthesized under the control of the virus may have been incorporated into the virus[7]. Nevertheless, the time course of Coxsackie *A*9 virus-induced RNA synthesis, as determined in the present investigation, is similar to that of synthesis of the infective RNA of Coxsackie *A*9 virus[8]. Thus, the results reported here contribute additional support for the view that enterovirus RNA synthesis precedes virus maturation by only a short time[9].

The demonstration that HBB inhibits virus-induced ribopolynucleotide synthesis confirms and clarifies the previous finding of inhibition of infective viral RNA production by HBB.

This work was aided by a grant from The National Foundation.

Specific Lipids produced by Sugar Beet infected with Yellowing Viruses

AFTER infection with beet yellows virus (SBYV) the older leaves of sugar beet (*Beta vulgaris* L.) become thickened, brittle and yellow, and develop red or brown necrotic spots. Infection with sugar beet mild yellowing virus (SBMYV), a virus unrelated to SBYV, produces an orange-coloured chlorosis of the older leaves with thickening and brittleness but without necrotic spots[1]. This communication is concerned with chromatographic differentiation of these viruses through characteristic lipids extracted from leaves.

Fully turgid mature leaves were collected from sugar beet plants grown in the field or in sterilized compost in a glasshouse. Material was taken from three fields near Cambridge, and in Bedfordshire from a trial consisting of commercial varieties and experimental breeding plants. Some plots had been inoculated with SBYV or SBMYV; control plots were uninoculated. Extracts were made from the yellowest parts of leaves showing SBYV or SBMYV symptoms, and were compared with similar extracts from leaves of apparently healthy plants. Acetone and light petroleum were used at room temperature to extract the lipids from about 500 mg of leaf. The extracts were applied to filter-paper treated with zinc carbonate: chromatograms were developed in two dimensions, then examined by daylight and under ultra-violet irradiation. Spots required for further examination were cut out and eluted into ethanol. The method has been briefly described[2] and is similar in extraction and chromatographic stages to that described in detail for the determination of α-tocopherol[3]. Some prominent lipids always found in healthy leaves, shown in Fig. 1, were used in locating lipids from leaves of virus-infected plants.

SBYV infection reduced the chlorophyll content and caused the appearance, on chromatograms prepared with extracts of leaves, of two prominent spots that fluoresced nearly white under each of two sources of ultra-violet irradiation having maximum emission at about 254 and 365 mμ respectively. The spectral absorption maxima in ethanol of the upper spot were at 243, 280 and 341 mμ and of the lower spot were at 243, 281 and 342 mμ. The lipids were produced in infected leaves of both field and glasshouse beet, but only in leaves that had turned yellow; they were not found in extracts from apparently healthy leaves of any age. These fluorescing lipids were not seen on chromatograms from green leaves of apparently healthy plants of 100 other species, nor on chromatograms from senescent leaves of several species. Two unrelated species, *Claytonia perfoliata* Donn., and *Chenopodium capitatum* Aschers, were grown in the glasshouse and inoculated with SBYV, but although the older infected leaves became prematurely yellow, the characteristic lipids found in SBYV-infected sugar beet leaves were not seen on chromatograms of their extracts.

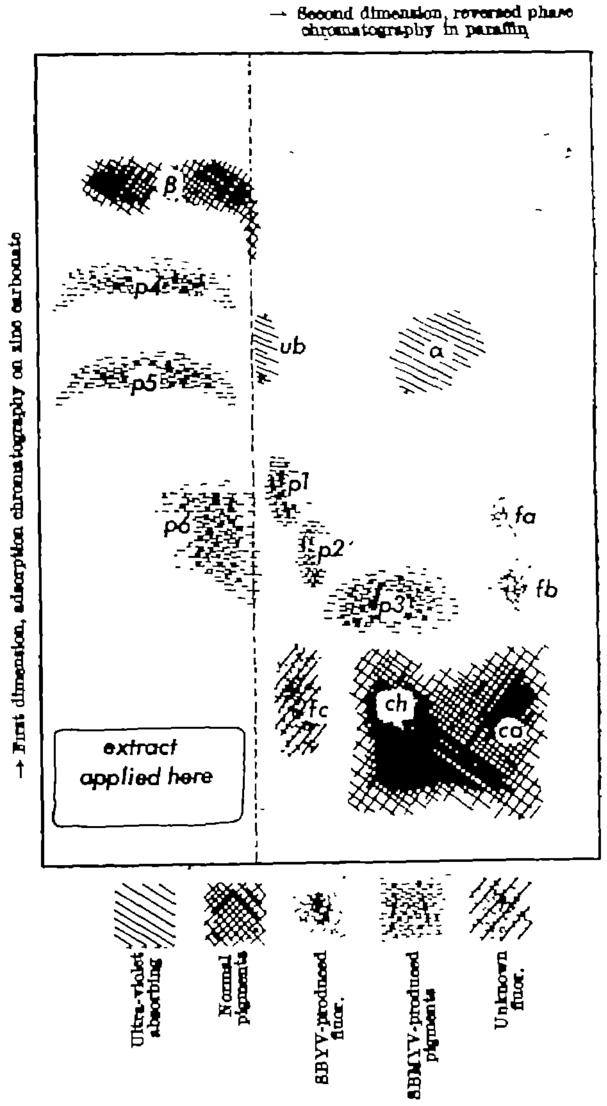

Fig. 1. Position on a two-dimensional chromatogram of phyllolipids extracted from leaves of sugar beet. Group I, lipids found in all leaves. *a*, α-tocopherol; β, β-carotene; *ch*, chlorophylls; *ca*, carotenols, *ub*, ubiquinone-50; group II, additional fluorescing lipids, *fa*, *fb*, from SBYV-infected leaves; group III, additional pigments *p*1–*p*6 from SBMYV-infected leaves; group IV, fluorescing lipid *fc* of unknown origin

SBMYV infection of field-grown beet also reduced the chlorophyll content, and caused the appearance of at least six yellow or orange pigments in addition to those found in healthy leaves. The positions of the most prominent pigments are shown on the chromatogram (Fig. 1). At least two other ill-defined yellow patches also appeared between the application area and pigment *p*6. Solubility and chromatographic behaviour of pigments *p*1–*p*6 were consistent with a carotenoid nature, and spectral absorption curves were characteristic of carotenoids. The pigments were tested for the presence of epoxide groups, by Curl and Bailey's method[4]: *p*6 gave a positive result in one min, *p*3 in 15 min, *p*5 in about an hour, whereas *p*1, *p*2 and *p*4 gave negative results. In some respects chromatograms of extracts from fully turgid orange leaves of SBMYV-infected beet resembled those of extracts from senescent leaves of uninfected plants. Leaf yellowing of SBMYV-infected sugar beet grown under glass was usually very slight, and the pigments were not always seen in this material.

On certain chromatograms, a strongly fluorescing spot was seen at *fc* (Fig. 1). This unknown fluorescing compound was found on about one-third of the chromatograms prepared from leaves of field-grown sugar beet, whether the plants were apparently healthy or were showing symptoms of SBYV, SBMYV or both. It was not seen in leaves of other species, nor was it obvious in preparations from leaves of beet grown under glass in sterilized compost. Its distribution was not correlated with any obvious symptoms, but it seems possible that those plants which produced this substance *fc* may have been infected with an unrecognized virus or other pathogen.

In the field, both yellowing viruses commonly occurred in the same plants, and leaf extracts from these showed the fluorescing spots characteristic of SBYV-infection, together with the pigments characteristic of SBMYV. From the experiments reported here it seems that SBYV produces specific fluorescing substances, and SBMYV produces pigments. This chromatographic method can therefore be used diagnostically. It also appears that the yellowing caused by SBYV resulted from the partial loss of chlorophyll without production of other pigments; whereas SBMYV caused some loss of chlorophyll but additional pigments were produced which gave the infected leaves their characteristic orange colour.

SOIL SCIENCE

Identification of Soil-fertilizer Reaction Products in a Calcareous Saskatchewan Soil by Infra-red Absorption Analysis

Bouldin and Sample[1] and Beaton and Read[2] reported that uptake of phosphorus from calcareous soils was greater from monoammonium phosphate (MAP) than from diammonium phosphate (DAP) treatments. The formation of relatively unavailable reaction products was believed to be responsible for the differences observed in the latter work. Identification of the soil-fertilizer reaction products formed from MAP and DAP would assist in understanding the responses obtained with these materials since plants obtain most of their fertilizer phosphorus from such reaction products.

The soil used in this investigation and in the earlier investigation[2] was the Bradwell very fine sandy loam which had the following properties: $pH = 7 \cdot 7$, 6·6 per cent calcium carbonate, 6 p.p.m. of sodium bicarbonate extractable phosphorus and 1·4 per cent total carbon. Saturated solutions of MAP and DAP were prepared at 5° C and reacted with this soil according to the procedure of Lindsay and Stephenson[3]. 150 ml. of the fertilizer solutions were each shaken with 300 g of air-dried soil for 15 min at 5° C. Filtrates obtained from these suspensions were stored at 5° C and were examined periodically to follow the progress of precipitation of solids as was outlined by Lindsay *et al.*[4].

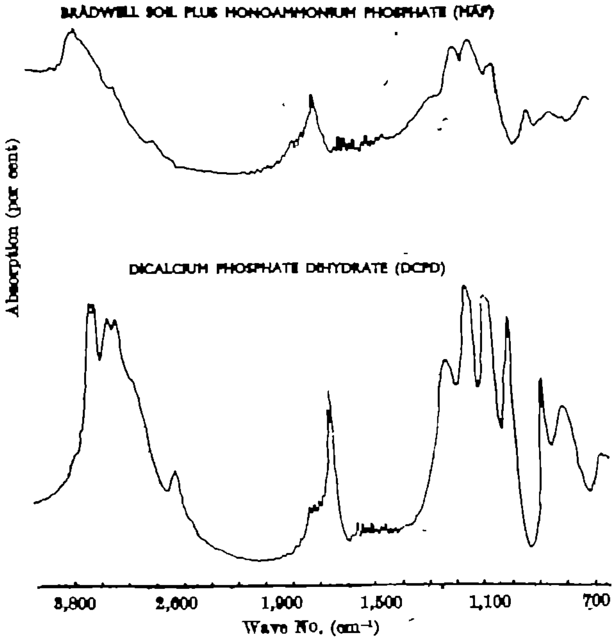

Fig. 1. Infra-red absorption spectra of monoammonium phosphate reaction product and dicalcium phosphate dihydrate

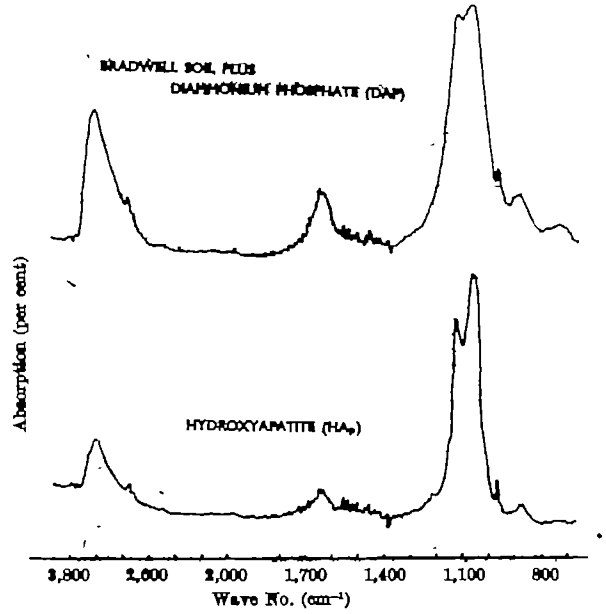

Fig. 2. Infra-red absorption spectra of diammonium phosphate reaction product and hydroxyapatite

At the end of 10 days the reaction products were collected, washed three times with distilled water and dried with acetone. Identification of the reaction products was attempted by X-ray diffraction; but this method failed apparently because the reaction products were too finely divided. However, infra-red absorption proved to be a satisfactory alternative method for identifying these materials.

Infra-red absorption spectra were obtained for a number of compounds that have been reported to be reaction products of MAP and DAP[4]. These spectra were compared with those of the soil-fertilizer reaction products. The spectra of MAP reaction product and dicalcium phosphate dihydrate (DCPD) are shown in Fig. 1. In Fig. 2 the spectra of DAP reaction product and hydroxyapatite are shown.

It is evident that the MAP reaction product and DCPD were similar while the DAP reaction product resembled hydroxyapatite. Our DCPD spectrum agreed closely with the brushite (DCPD) spectrum obtained by Jones and Cruickshank[5].

From these results it appears that the major initial reaction products of MAP and DAP in the Bradwell soil were DCPD and hydroxyapatite, respectively. Further investigations are being conducted to determine if infra-red absorption analysis can be used to identify reaction products from other fertilizers and soils.

MISCELLANEOUS

Estimating the Thickness of Pulped Wood Fibres

IN examining the mechanical properties of dry, pulped wood fibres which comprise most papers, the dimensions of the fibres must be known. For quantitative purposes, their cross-sectional shape (Fig. 1) is best represented by the rectangle. The 'width' of the fibre is readily measured by the micrometer eyepiece of a microscope as is the length, the largest dimension by orders-of-magnitude. However, the thickness of the fibre is awkward to measure for a number of reasons:

(1) The thickness is in the μ range.

(2) The thickness is generally non-uniform at any one point along the length of the fibre because of the incompleteness of collapse; vestiges of the lumen are generally present along the edges. (Wood fibres are initially more or less circular, but the large pressures applied in the paper-making process cause their collapse.)

(3) Appreciable variations exist in the cross-sectional shape and thickness along the length of the fibre.

(4) Dimensional variations among fibres of any one pulp are extremely large.

(5) The top and bottom of fibres are difficult to define.

Clearly such conventional techniques for measuring the thickness of microscopic-sized particles as the vertical focusing of a microscope stage are unsatisfactory. The use of cross-sections, which require embedding, introduce an additional uncertainty in the possible changes in dimensions caused by swelling and microtoming. Thus a precise technique is not available.

We have applied two techniques, entirely different from each other, which give essentially the same results. These techniques have the further advantage of being quite rapid.

(1) *Retardation Method.* The cellulose chains in wood are aligned more or less parallel to each other and the central fibre axis: hence, fibres are birefringent. When examined between crossed Nicols and a first-order quartz retardation plate, fibres exhibit first-order retardation colours. The equivalent wave-length of the retardation colours, R, is related to the thickness of the cellulose of the fibre (double the wall-thickness), $\bar{\delta}$, by the relationship, $\bar{\delta} = R/(\eta_\gamma - \eta_\alpha)$, where η_γ and η_α are the indices of refraction parallel and perpendicular, respectively, to the principal axes of the fibre[1-3].

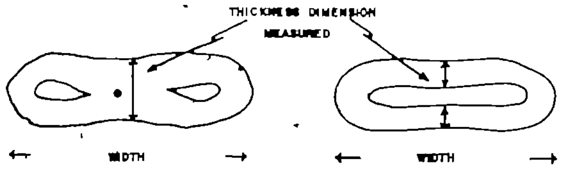

Fig. 1. Typical cross-sectional shapes of fibres

In the investigation recorded here we noted the colour of the central portion of the fibres where pits were absent. The selection of points of measurements is described later. Each value reported in Table 1 is the average of 200 measurements, requiring about 2 h.

(2) *Density Method.* Assuming fibres to have a rectangular cross-section, $\bar{\delta}$ can be calculated from the density equation, $\bar{\delta} = w/\gamma\bar{\omega}$, where w is the mean weight per unit length of fibre; γ, the density of cellulose; and $\bar{\omega}$, the mean fibre width. w, γ, and $\bar{\omega}$ are easily measured.

We measured γ of standard handsheets[4] with a Beckman air comparison pycnometer, model 930. In this instrument, the volume displaced by cellulose is measured.

Using 0·05 g of pulp instead of 1·2 g and large pressures in the standard sheet-forming process[4], ultra-thin (2–*D*) sheets were produced, the fibres of which are clearly visible. We scanned along a straight line of the 2–*D* sheets, noting the width and retardation colour of every fibre. w was calculated from the equation $w = 2W/(1{\cdot}1)\pi(N/L) = 0{\cdot}578W/(N/L)$, where W is the weight per unit area of the sheet; N, the number of fibres intersected in scanning along a line of length L; and 1·1, a factor taking into account the slight curvature of the fibres[5]. Three 15-cm scans, 60° apart, were made on each sample. A complete determination, excluding the retardation measurements, takes about 2 h. The results of the measurements on eight pulps are shown in Table 1. Agreement between the results of the two techniques is surprisingly good.

Table 1

Pulp	γ (g/cm³)	w (g/cm) × 10⁶	$\bar{\omega}$ cm × 10³	$\bar{\delta}$ cm × 10⁴ Retardation method	Density method
Spruce sulphite	1·63	1·3	3·7	2·7	2·2
Spruce kraft No. 1	1·60	1·5	3·5	2·6	2·7
Spruce kraft No. 2	1·60	1·4	3·5	2·6	2·5
Spruce magnifite	1·60	1·5	3·7	2·4	2·5
Southern pine kraft (U.S.)	1·59	2·2	4·5	3·5	3·1
Western mixed softwood kraft U.S.)	1·56	1·6	3·5	3·4	2·9
Jack pine	1·62	1·5	3·3	3·0	2·8
Mixed bleached hardwood	1·59	1·2	2·0	3·8	3·6

All samples mechanically untreated.

The retardation method requires a high-quality microscope and considerable training, but the density method involves only generally available equipment; where a pycnometer is not available, a value of = 1·6 g/cm³ can be used confidently. Thus the density technique is a simple and rapid means of estimating the wall thickness of pulped wood fibres.

FORTHCOMING EVENTS

Monday, April 1

Royal Institution (at 21 Albemarle Street, London, W.1.), at 5.30 p.m.—Mr. Norris D. McWhirter: "Facts and How to Find Them".

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Passenger Handling Within Large Buildings".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"Tribes of the Xingu"—Films with commentary by Mr. Adrian Cowell.

Society of Chemical Industry, London Section (at 14, Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. H. Coates. "Modern Aspects of Phosphorus Compounds".

Tuesday, April 2

Polarographic Society (in the Optics Lecture Theatre of the New Physics Department, Imperial College, Prince Consort Road, London, S.W.7), at 2.30 p.m.—Meeting on "Polarography in the Teaching of Analytical Chemistry". 4 p.m.—Annual General Meeting.

Institution of Electrical Engineers, Science and General and Power Divisions (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. K. Wright and Mr. P. D. Dunn: "New Methods for the Generation of Electricity".

Plastics Institute (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Symposium on "The Mixing of Thermo-plastic Materials".

Tuesday, April 2—Wednesday, April 3

Faraday Society (at Queen's College (University of St. Andrews), Dundee), at 9.30 a.m. daily—General Discussion on "The Structure of Electronically-Excited Species in the Gas Phase". Chairman: Prof A. R. Ubbelohde, F.R.S.

Tuesday, April 2—Thursday, April 4

British Society for Parasitology (in the Zoology Department, University College of Wales, Aberystwyth)—Spring Meeting.

Wednesday, April 3

Colour Group (Great Britain) (in the Physics Department, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 10 a.m.—Symposium in "The Colorimetry of Near Whites". 2 p.m. to 5 p.m.—Exhibition of Colorimeters, Spectrophotometers, Light Sources, Colour Atlases, Colour Filters, Colour Vision Tests and allied equipment. 5.30 p.m.—Prof. W. D. Wright: "The Rays are not Coloured" (First Newton Lecture).

Iron and Steel Institute, Iron and Steel Engineers Group (at 4 Grosvenor Gardens, London, S.W.1), at 10 a.m.—Discussion Meeting on "Universal Beams".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. D. J. Blundell, Dr. R. F. King and Dr. O D. V. Wilson: "Seismic Investigations of the Rocks Beneath the Northern Part of Cardigan Bay"; Dr. J. L. Daniels, Dr. W. J. Skiba and Dr. J. Sutton: "The Deformation of some Banded Gabbros in the Northern Somalia Fold-Belt".

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m —Mr. S. Elder: "The Umm Shaif Oilfield: The History of Its Exploration and Development".

Institution of Electrical Engineers, Power Division P G.P7 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. A. B. Madin and Mr. J. D. Whitaker. "The Dynamic Behaviour of a Transformer Winding under Axial Short-Circuit Forces—an Experimental and Theoretical Investigation".

British Institution of Radio Engineers, Radar Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. G. E. Roberts, Mr. B. Parker and Mr. C. Powell: "The Display and Processing of Data from the Harco Navigation System"

Wednesday, April 3—Friday, April 5

Society of Chemical Industry, Agriculture Group (in Churchill Hall and the Engineering Laboratory Lecture Theatre, University of Bristol)—Symposium on "Soil Analysis and Its Relation to Plant Composition and Growth".

Thursday, April 4

Institution of Mechanical Engineers, Process Engineering Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 10.30 a.m.—All-day Symposium on "Dust Control and Air Cleaning".

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. B. T. M. Willis: "Neutron Diffraction Studies of the Actinide Oxides".

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. William S. Lacey· "A Possible Eleutherophyllum from Lower Carboniferous of North Wales"; Dr. John Attridge: "Triassic Vertebrates of Central Africa".

Institute of Refrigeration (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 5.30 p.m.—Mr. K. Fowler "Air-Conditioning of Large Buildings".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2) at 5.30 p.m.—Mr. P L. Taylor: "Mathematics as an Educational Discipline for the Engineer".

Society of Chemical Industry, Microbiology Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting.

Society of Chemical Industry, London Section (joint meeting with the Mid-Southern Counties Section of the Royal Institute of Chemistry and the Plastics Institute at the University, Southampton), at 7.30 p.m.—Mr. K. C. Bryant. "Polymers—Old and New".

Institute of Metals (at 14 Belgrave Square, London, S.W.1), at 9 p.m.—Annual General Meeting, followed by The Viscount Boyle. "Architectural Metalwork".

Thursday, April 4—Friday, April 5

Mineralogical Society, Clay Minerals Group (at Plymouth Technical College, Tavistock Road, Plymouth)—Spring Meeting.

Friday, April 5

Royal Society of Medicine, Anaesthetics Section (at 1 Wimpole Street, London, W.1), at 6 p.m.—Dr. P. W. Nathan and Dr. T. A. Sears: "The Susceptibility of Nerve Fibres to Local Anaesthetics"; Dr. Ian Verner: "Some Problems of the Clinical Evaluation of Relaxant Drugs in Man, with special reference to a New Competitive Agent".

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting. Prof. R. A. Raphael, F.R.S.: "Acetylenic Chemistry".

Monday, April 8

Institution of Electrical Engineers, Science and General Division P.Gs. 31 and 32 (at Savoy Place, London, W.C.2)), at 5.30 p.m.—Discussion on "Applications of Superconducting Materials" opened by Dr W. F. Gauster, Dr. P. F. Chester, Dr. D. R. Chick and Dr. G. W. Wilson.

Royal Geographical Society (at 1 Kensington Gore, London, S W.7), at 8.30 p.m.—Mr. Charles A. Morris and Mr. A. C. Barrington-Brown. "Cambridge Expedition to South-East Asia".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer, Grade "B" (with a good honours degree in biological subjects, teaching experience, and preferably an interest in field work), to teach Botany and Zoology for General Certificate of Education Advanced Level and Zoology for the Ordinary Endorsed Certificate in Biology—The Principal, Acton Technical College, High Street, Acton, London, W.3 (April 6).

Lecturer or Assistant Lecturer in Numerical Analysis in the Department of Applied Mathematics—The Registrar, The University, Liverpool, quoting Ref. No. CV/231/N (April 6).

Research Assistant (with a good honours degree or diploma in technology and in mathematics, and preferably an interest in research in numerical analysis and statistics) in the Department of Mathematics—The Registrar, Department 27/E, Bradford Institute of Technology, Bradford 7 (April 6).

Scientific Assistant, to work on chemical and biochemical problems in the carbohydrate field—The Secretary, Royal Holloway College, Englefield Green, Surrey (April 6).

Lecturer (with a registrable medical qualification) in Physiology—The Registrar, Trinity College, Dublin 2, Republic of Ireland (April 8).

Programmer in the Department of Mathematics, to be concerned with the preparation of programmes for an English Electric KDF 9 Computer, which is to be installed in August 1963—The Secretary, Royal College of Advanced Technology, Salford 5, Lancs, quoting Ref. MA/6 (April 8).

Research Assistant (physicist or electrical engineer with a Ph.D. or equivalent research experience) in the Department of Electrical Engineering, to study processes associated with arc movement in a magnetic field—The Registrar, The University, Leeds, 2 (April 8).

Research Fellow in Pure Science—The Registrar and Secretary, The University, 38 North Bailey, Durham (April 8).

Assistant Lecturer in Social Anthropology and Sociology—The Registrar, The University, Manchester 13 (April 10).

Assistant Lecturers (3) (graduates in either metallurgy, physical chemistry, chemical engineering or physics) in the Department of Metallurgy—The Registrar, The University, Manchester 13 (April 10)

Lecturer or Assistant Lecturer (preferably with experience in communications, vacuum tubes, plasma physics or some other branch of electronics) in Electronics Engineering—The Registrar, University College of North Wales, Bangor, North Wales (April 10).

Research Assistant (with good qualifications in mathematics and preferably a knowledge of computing methods) to the Professor of Applied Mathematics, to assist with the analysis of magnetic observations made during the IGY—The Secretary, The University, Northcote House, The Queen's Drive, Exeter, Devonshire (April 11).

Biologist—Vermin Control (with a degree in science with a major in zoology or in agricultural science with postgraduate zoological experience, or equivalent)—in the Department of Agriculture, initially at Perth, to undertake biological work on the natural history, bionomics, ecology and physiology of pest or potential pest animals and birds—Public Service Commissioner, 184 St. George's Terrace, Perth, Western Australia (April 12).

Lecturer (preferably with an interest in insect physiology) in Zoology (Comparative Physiology) at the Royal College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 12).

Research Fellow or Junior Research Fellow (with a sound statistical background, and capable of planning, executing and analysing mobility surveys) in Sociology at the Institute of Social and Economic Research, University of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 12).

Assistant Lecturer in the Department of Philosophy—The Registrar, The University, Leicester (April 13).

Lecturer in the Department of Mathematics—The Secretary, The University, Aberdeen (April 13).

TEMPORARY ASSISTANT LECTURER or TEMPORARY LECTURER IN THE DEPARTMENT OF PHYSICS—The Registrar, The University, Liverpool, quoting Ref. No. CV/287/N (April 18).

ASSISTANT LECTURER (preferably with some interest either in acoustics or in ionizing radiation) IN EXPERIMENTAL PHYSICS—Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (April 17).

LECTURER IN THE DEPARTMENT OF ANIMAL GENETICS—The Secretary, The University, Edinburgh (April 17).

LECTURER IN APPLIED MATHEMATICS—The Secretary, The Queen's University, Belfast, N. Ireland (April 19).

LECTURER IN INORGANIC AND ANALYTICAL CHEMISTRY—The Secretary, The Queen's University, Belfast, Northern Ireland (April 19).

LECTURER or ASSISTANT LECTURER IN PHYSICS—The Secretary, The Queen's University, Belfast, Northern Ireland (April 19).

LECTURER or ASSISTANT LECTURER IN SOCIAL ANTHROPOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (April 19).

LECTURER (preferably with postgraduate experience in any of the following fields: (*a*) physical organic chemistry; (*b*) spectrophotometry; (*c*) free radical chemistry; or (*d*) high molecular weight materials) IN ORGANIC CHEMISTRY—Head of the Department of Chemistry, Northampton College of Advanced Technology, St. John Street, London, E.C.1 (April 19).

CHAIR OF GEOGRAPHY; SENIOR LECTURERS, LECTURERS or ASSISTANT LECTURERS IN GEOGRAPHY AND GEOLOGY at the University of Ife, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 20).

LECTURER (man or woman) IN PSYCHOLOGY AND MATHEMATICS—The Principal, Borough Road College, Isleworth, Middlesex (April 20).

POSTDOCTORAL RESEARCH FELLOW (preferably with a knowledge of many-electron atom theory and of computing) IN THEORETICAL CHEMISTRY, to work with Dr. H. O. Pritchard on exact calculations for lithium and beryllium using the Atlas Computer—The Registrar, The University, Manchester 13 (April 20).

PRINCIPAL PHYSICIST (with good academic qualifications (preferably including a higher degree) and several years experience in scientific research or development) IN THE REGIONAL PHYSICS DEPARTMENT, to be in charge of a section providing advice and scientific help on the application of radioactive isotopes in clinical research; most of this work is done in teaching hospitals and university departments—The Secretary, Western Regional Hospital Board, 351 Sauchiehall Street, Glasgow, C.2 (April 20).

SENIOR LECTURER (with a degree in either medicine, pharmacology or pharmacy, and previous experience in either teaching or industrial research) IN PHARMACOLOGY at Kwame Nkrumah University of Science and Technology, Kumasi, Ghana—The Assistant Registrar, Kwame Nkrumah University of Science and Technology, 15 Gordon Square, London, W.C.1 (April 23).

OFFICIAL FELLOW IN CHEMISTRY—The Principal, Hertford College, Oxford (April 24).

TECHNICIAN (male or female, F.I.M.L.T., with extensive experience in histological techniques) IN THE DIAGNOSTIC SECTION, Agriculture Department, Ruakura Animal Research Station, New Zealand, to take charge of the Histological Laboratory of the Diagnostic Section—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. B 13/2/14/652 (April 24).

PROFESSOR OF AGRONOMY; and a SENIOR LECTURER/LECTURER or TEMPORARY LECTURER OF PARASITOLOGY in the Faculty of Rural Science, University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 26).

UNIVERSITY STUDENTS and FELLOWS for experimental or theoretical research in nuclear and elementary particle physics—The Professor of Natural Philosophy, The University, Glasgow, W.2 (April 27).

LECTURERS (2) (with qualifications in either pure mathematics or applied mathematics) IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Bristol 8 (April 29).

GORDON CRAIG FELLOW (graduate in medicine) IN UROLOGY—The Registrar, University of Sydney, Sydney, New South Wales, Australia (April 30).

LECTURER (well qualified in electrical engineering or science) IN ELECTRICAL ENGINEERING at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 30).

LECTURER (with experience in agricultural physics or soil physics) IN SOIL SCIENCE at the University of Sydney, Australia—The Association of Universities of the British Commonwealth (Branch Office), Pall Mall, London, S.W.1 (Australia and London, April 30)

READER IN ELECTRON MICROSCOPY IN THE DEPARTMENTS OF BOTANY, MICROBIOLOGY AND ZOOLOGY—The Registrar, University of Adelaide, Adelaide, South Australia (April 30).

RESEARCH ASSISTANT, Assistant Experimental Officer grade (with a chemical background, and a pass degree or equivalent qualifications) IN THE DEPARTMENT OF POTATO GENETICS, to help in biochemical investigations in potatoes—The Secretary, John Innes Institute, Bayfordbury, Hertford, Herts. (April 30).

RESEARCH WORKER, Scientific Officer grade (with biological, medical or veterinary training and preferably experience in virology or bacteriology), to join a team studying avian respiratory diseases—The Secretary, Houghton Poultry Research Station, Houghton, Huntingdon (April 30).

SENIOR LECTURER IN MATHEMATICS; and a LECTURER IN MATHEMATICS—The Registrar, University of Adelaide, Adelaide, South Australia (April 30).

SENIOR LECTURER (preferably with experience in educational and vocational guidance and counselling, or in clinical psychology) IN PSYCHOLOGY at the University of Melbourne, Australia—The Secretary. Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 30).

SENIOR LIBRARIAN (with the A.L.A. qualification and preferably with experience in a special library concerned with biology or agriculture)—The Director, Commonwealth Institute of Entomology, 56 Queen's Gate, London, S.W.7 (April 30).

SENIOR RESEARCH ASSOCIATE (experienced solid state physicist), to carry out research on radiation damage and defects in ionic crystals—The Registrar and Secretary, King's College (University of Durham), Newcastle upon Tyne (April 30).

UNIVERSITY DEMONSTRATOR (with interests in the economic aspects of geography) IN THE DEPARTMENT OF GEOGRAPHY—Dr. I. D. Muir, Department of Mineralogy and Petrology, The University, Downing Place, Cambridge (April 30).

OPPENHEIMER RESEARCH SCHOLARS (suitably qualified graduates in geology) IN THE RESEARCH INSTITUTE OF AFRICAN GEOLOGY, for work which will lead to a Ph.D., and will be done partly in Africa and partly in Leeds—Prof. W. Q. Kennedy, Department of Geology, The University, Leeds 2 (May 1).

PROFESSOR OF MATHEMATICAL PHYSICS; a LECTURER IN BOTANY; a LECTURER IN CHEMISTRY; a LECTURER IN MATHEMATICAL PHYSICS; and a LECTURER IN MATHEMATICS—The Secretary, University College, Galway, Republic of Ireland (May 8).

TUTORIAL RESEARCH FELLOW or STUDENT (man or woman graduate) IN CHEMISTRY, for duties which will include supervision of laboratory classes, time will be available for independent research—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (May 10).

CHAIR OF CHEMICAL ENGINEERING within the Faculty of Engineering at Monash University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia (Australia and London, May 15).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF ORGANIC CHEMISTRY—The Registrar, The University, Leeds 2 (May 25).

LECTURER (with an honours degree in physics or equivalent qualifications) IN PHYSICS at Wollongong University College—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Australia (May 31).

ASSISTANT PHYSICIST (Senior or Basic grade) IN THE COUNTY MEDICAL PHYSICS DEPARTMENT—The Secretary, St. George's Hospital, Lincoln.

CHAIR OF THEORETICAL PHYSICS—The Registrar and Secretary, The University, Bristol.

EXPERIENCED MATHEMATICIAN capable of teaching up to "S" level—The High Master, Manchester Grammar School, Manchester 13.

GRADUATE TEACHING AND RESEARCH ASSISTANTSHIPS leading to M.Sc. and Ph.D. degrees—Head, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada.

LABORATORY TECHNICIAN, Grade II (aged 21 or over)—The Head Master, King Edward VI School, Southampton.

LECTURER or SENIOR LECTURER IN MATHEMATICS IN THE TRAINING DEPARTMENT—The Warden, University of London Goldsmiths' College, New Cross, London, S.E.14.

MASTER TO TEACH MATHEMATICS AND CHEMISTRY at Sixth Form level—The Headmaster, Greshams School, Holt, Norfolk.

POSTDOCTORAL RESEARCH FELLOW IN THEORETICAL NUCLEAR PHYSICS, for work involving the investigation of the structure of nuclei and hyperfragments—Head, Department of Physics, Battersea College of Technology, London, S.W.11.

READER (with considerable research experience) IN ELECTRICAL ENGINEERING—Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

RESEARCH ASSISTANT IN MYCOLOGY—The Secretary, Wright-Fleming Institute, St. Mary's Hospital Medical School, Paddington, London, W.2.

RESEARCH ASSISTANT (graduate chemist or biochemist) IN THE ARTIFICIAL KIDNEY UNIT—The House Governor, The London Hospital, Whitechapel, London, E.1.

RESEARCH ASSISTANT (preferably with experience in autoradiography, embedding and section cutting for the electron microscope), for cytological work in algae in collaboration with Dr. M. B. E. Godward—The Registrar, Queen Mary College (University of London), Mile End Road, London, E 1.

RESEARCH DEMONSTRATOR (with a good degree in horticulture or botany) IN THE DEPARTMENT OF HORTICULTURE, to assist with practical classes in plant physiology—Prof. O. V. S. Heath, F.R.S., University of Reading. Horticultural Research Laboratories, Shinfield Grange, Shinfield, Berks.

SENIOR LECTURER IN THEORY OF MACHINES AND MACHINE DESIGN; LECTURER IN MATHEMATICS, an ASSISTANT LECTURER (Grade B) IN BOTANY, an ASSISTANT LECTURER (Grade B) IN PHYSICS; an ASSISTANT LECTURER (Grade B) IN ELECTRICAL ENGINEERING (heavy current); and an ASSISTANT LECTURER (Grade B) IN MARINE RADIO, at the College of Technology, Kingston upon Hull—The Chief Education Officer, Guildhall, Kingston upon Hull.

SENIOR LECTURER or LECTURER IN TEXTILE CHEMISTRY—The Secretary, Royal College of Science and Technology, George Street, Glasgow, C.1.

SENIOR LECTURER (with a higher degree together with an effective knowledge of food processing methods) IN FOOD SCIENCE—The Secretary, Royal College of Science and Technology, Glasgow, C.1.

SENIOR II TECHNICIAN (with biochemical experience), for duties which will include the supervision of student technicians, supplies and storekeeping, and carrying out specialized biochemical investigations for diagnosis and research—Dr. G. H. Spray, Nuffield Department of Medicine. Radcliffe Infirmary, Oxford.

TECHNICIAN (preferably A.I.M.L.T., A.I.S.T., or equivalent status, and some experience in haematology) IN THE DEPARTMENT OF SURGICAL SCIENCE, to assist in research on tissue transplantation—The Secretary, Department of Surgical Science, University of Edinburgh Medical School, Teviot Place, Edinburgh 8, quoting Ref. No. T/88/3/63.

APPOINTMENTS VACANT

UNIVERSITY OF BRISTOL

CHAIR OF THEORETICAL PHYSICS

The University is establishing a Chair of Theoretical Physics from August 1, 1963, and proposes to make an appointment thereto as soon as possible.

Suitably qualified candidates are invited to submit applications, including the names and addresses of referees, to the undersigned, from whom further particulars of the appointment may be obtained.

H. C. BUTTERFIELD,
Registrar and Secretary.

KWAME NKRUMAH UNIVERSITY OF SCIENCE AND TECHNOLOGY

KUMASI, GHANA

FACULTY OF PHARMACY

Applications are invited for the post of

SENIOR LECTURER

in Pharmacology.

Qualifications:

Applicants should hold a degree in either Medicine, Pharmacology or Pharmacy and should have previous experience in either teaching or industrial research.

Duties:

Successful candidates will be expected to teach up to the level of the general Degree in Pharmacy of the University. In addition to teaching duties, candidates will be expected to participate in a research programme of investigation of the Medicinal and toxic plants of Ghana. This programme is being carried out in conjunction with the Chelsea College of Science and Technology, London.

Salary Scale:

Ghanaian Senior Lecturer, £G.1,750 by £G.75 to £G.2,200 per annum.

Non-Ghanaian Senior Lecturer, £G.2,100 by £G.90 to £G.2,640 per annum.

Entry at appropriate point.

Appointments are normally for five years in the first instance and may be renewed; one term's notice of resignation or termination of appointment is required on either side. Outfit allowance £G 60 (where applicable). Car maintenance allowance £G.150 per annum. Children's allowances are paid in respect of expatriates at the rate of £G.50 per annum per each child resident in Ghana and £G.100 per annum per each child in full-time education overseas up to a maximum of 21 years of age (maximum: five children). Accommodation with basic furniture. Rent not exceeding £G.150 per annum. F.S.S.U. policies maintained if already held or superannuation on similar basis.

Annual leave with three free return passages in every four years for non-Ghanaians and families and one in every three years for Ghanaians.

Application forms and further information may be obtained from the Assistant Registrar, Kwame Nkrumah University of Science and Technology, 15 Gordon Square, London, W.C.1. Completed application forms should reach the above-mentioned address not later than April 23, 1963

UNIVERSITY OF CAMBRIDGE

DEMONSTRATOR IN GEOLOGY

Applications are invited for the post of University Demonstrator in the Department of Geology, tenable from October 1, 1963, for three years in the first instance. Applicants should have interests in palaeontology, stratigraphy, sedimentary petrology, or structural geology. Salary scale (now under review): £1,000 by £50 to £1,250. Membership F.S.S.U. and Children's Allowance Scheme.

Further details may be obtained from Dr. I. D. Muir, Department of Mineralogy and Petrology, Downing Place, Cambridge, to whom applications (including the names of two referees), should be sent by May 18, 1963.

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF CHEMICAL ENGINEERING

Applications are invited for the undermentioned positions with the Organization's Division of Chemical Engineering at Fishermen's Bend, Melbourne, Victoria.

The Division of Chemical Engineering undertakes fundamental and applied investigations into fields of process and equipment development and unit operations research. Subjects covered include: water desalination, gasification of coal, comminution, fluidization, mixing and mass transfer operations.

CHEMIST OR CHEMICAL ENGINEER

(No. 608/27)

The appointee will be required to undertake fundamental and applied research in various fields of physical chemistry and chemical engineering. Initially work would be undertaken on a promising new method for the prevention of scale formation on the heating surfaces of evaporators (e.g., in water desalination equipment), by the introduction of selected polymeric compounds which form regenerating protective films. This would involve the building up of a small team to prepare and characterize suitable polymers, and to examine their behaviour under both practical and idealized laboratory conditions.

Applicants should possess at least a University honours degree in Science with Chemistry as a major subject, or in Chemical Engineering, together with some years of postgraduate research experience. An interest, or experience in physical or surface chemistry would be of particular value.

CHEMICAL ENGINEER

(No. 608/34)

The appointee will be required:

(a) To undertake work on plant design, and evaluation and costing of proposed new processes.

(b) To carry out investigations into applications of computer techniques to process design.

The work will be mainly of a theoretical nature, but the opportunity will arise from time to time to take part in experimental investigations.

Applicants should possess at least a Degree in Chemical Engineering with first- or second-class honours, together with some years of postgraduate research experience. Additional experience in process design and/or the commissioning of plant would be desirable.

SALARY: Dependent on qualifications and experience, salary for both positions will be determined within the ranges

£A1,541 to £A2,296 per annum or £A2,426 to £A2,751 per annum

Salary for women will be £A188 per annum less than corresponding rates for men.

Promotion within C.S.I.R.O. is by merit and may go beyond the upper limit of the scale within which the original appointment is made.

By mutual arrangement, the appointments may be for an indefinite period or for a fixed term of three years. In the case of a fixed term appointment consideration will be given to the continuation of F.S.S.U. or alternatively, if a secondment is arranged with the present employer, the Organization may reimburse the employer's share of other superannuation schemes.

Fares paid for the appointees and their dependent family and return fares to point of origin will be paid for an appointee who accepts appointment for a fixed term. Further particulars supplied on application to:

Mr. P. F. Butler, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2,

to whom applications (quoting the relevant appointment number), should be addressed by May 25, 1963

GRADUATE ASSISTANTSHIPS IN BIOCHEMISTRY

Teaching and research assistantships leading to M.Sc. and Ph.D. degrees available for academic year 1963–64. Modern laboratories with excellent facilities. Wide variety of research projects. Stipend for teaching assistantships up to $3,200 plus travel allowance. Stipend for research assistantships $1,960 to total of $2,360 for twelve months.

Apply Head, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada.

JOHN INNES INSTITUTE REQUIRE A RESEARCH Assistant with chemical background to help in biochemical investigations in potatoes in the Department of Potato Genetics. The appointment will be in the Assistant Experimental Officer grade, and a Pass Degree or equivalent qualifications is required. Salary will be in the range £622 to £1,022 per annum, according to age and experience. Superannuation.—Applications, with the names of two referees, should be addressed to the Secretary, Bayfordbury, Hertford, Herts, not later than April 30, 1963.

HOUGHTON POULTRY RESEARCH STATION

Applications are invited for a research worker with biological, medical or veterinary training preferably with experience in virology or bacteriology to join a team studying avian respiratory diseases. Grading Scientific Officer (£768 to £1,721 per annum) or Senior Scientific Officer (£1,396 to £1,720 per annum), according to qualifications and experience. Superannuation under F.S.S.U.

Applications, with names of three referees, to the Station Secretary, Houghton, Huntingdon, before April 30.

ELECTRON MICROSCOPE UNIT, DEPARTMENT of Zoology, require person who should preferably be able to assist both with the research and the general running of an electron microscope. Salary in the range £785 to £1,335, plus London weighting.—Applications, in writing, stating qualifications, age and experience, should be sent to the Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, E.C.1.

N.V. PHILIPS' GLOEILAMPENFABRIEKEN
EINDHOVEN

Applications are invited for the post of

chief of the application laboratory for electron microscopy

Duties include research into the application of the Electron Microscope in biological and allied fields and assistance in the development of new instruments and accessories.

The successful applicant will supervise a laboratory in which demonstrations and instruction in the use of Electron Microscopes are given. He will also be expected to deliver lectures and to act as a source of information on the general techniques applicable in this field.

In view of the international character of the work knowledge of languages in addition to English is desirable but not absolutely essential.

Address applications to the Personnel Department N.V. Philips' Gloeilampenfabrieken, Willemstraat 20, Eindhoven, Holland, under number 63015.

SK&F

have vacancies for

LABORATORY TECHNICIANS

Suitable applicants will be able to conduct routine analyses as applied to raw materials and products of the pharmaceutical and allied industries.

Candidates should have some industrial experience and an interest in the use of instrumentation and semi-automatic methods.

Starting salaries will be commensurate with the experience of the applicants and the responsibility attached to these positions in an expanding field of interest. Thereafter salary progression is on a merit basis by means of annual reviews.

Other benefits offered by the Company include a non-contributory Pension and Life Assurance Scheme, good Cafeteria, and active Sports and Social Club.

Those interested are invited to write or phone for an application form from:

SK&F

The Recruitment Officer,
SMITH KLINE & FRENCH
LABORATORIES LIMITED,
Mundells, Welwyn Garden City, Herts.

Quoting Ref. No. T4005

THOMAS DE LA RUE INTERNATIONAL LIMITED

which is internationally known for its activities in many fields, particularly banknote and other security printing, has a vacancy in its Research Division near Maidenhead for a

GRADUATE PHYSICIST OR PHYSICAL CHEMIST

to carry out studies in printing plate manufacture and electronic control devices. The candidate should have studied Electronics as a subsidiary subject. Previous research experience is desirable.

Salary will be in line with the importance attached to this post and will be commensurate with qualifications and experience. There are many ancillary benefits, including a staff superannuation scheme.

Applications, stating age, education, experience, and present salary, should be sent to:

Chief Personnel Officer,
Thomas De La Rue International Limited,
110 Bunhill Row, London, E.C.1.

UNIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE

LECTURESHIP IN PSYCHOLOGY

Applications are invited for appointment to a Lectureship in Psychology. A good honours degree in psychology is required and applicants should preferably have university teaching experience and a research degree or research experience. The post will involve responsibility for laboratory practical courses.

Applications (six copies), containing the names of three referees, should be received not later than May 4, 1963, by the Registrar, University College, Cardiff, from whom further particulars may be obtained.

E. R. EVANS,
Registrar.

Cathays Park,
Cardiff.

THE ROYAL COLLEGE

NAIROBI

Applications are invited for newly created Chair of Pathology in Faculty of Veterinary Science. Appointee expected to develop Department in all aspects, but with special reference to gross pathology, histopathology, and food hygiene. Salary: £2,600 per annum. (Revision of salary scales under consideration.) Expatriate allowance £400 per annum. Permanent or contract terms (contract terms carry 25 per cent gratuity). F.S.S.U. Education allowance. Housing at subsidized rental. Passages for appointee and family (up to five adult passages) on appointment, termination and leave (three months every 21 months).

Detailed applications (eight copies), naming three referees, by May 31, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF BRITISH COLUMBIA

DEPARTMENT OF ZOOLOGY

VANCOUVER 8, B.C., CANADA

Applications are being sought for a post as Physiologist effective September 1, 1963. The appointment will be made at the Assistant Professor rank (salary $7,000 to $8,400 per annum, plus superannuation, insurance and fully comprehensive medical benefits). Teaching duties will include a course in elementary vertebrate physiology at the undergraduate level. The pursuit of an active programme of research and graduate student training are also essential. Persons will be considered irrespective of the field (vertebrate or invertebrate) but candidates with interests in nerve, muscle, cellular and general physiology will be particularly welcome. Curriculum vitae, publication list, a brief outline of current activities and a list of three referees should be submitted before April 30, 1963. References will only be sought in the cases of applicants who are short-listed for the appointment.

Applications should be addressed to: The Chairman, Department of Zoology, University of British Columbia, Vancouver 8, B.C., Canada.

UNIVERSITY OF EDINBURGH

DEPARTMENT OF ANIMAL GENETICS

LECTURESHIP

Applications are invited for the post of Lecturer in the Department of Animal Genetics. Salary scale (under review): £1,150 by £50 to £1,350; bar: £1,400 by £50 to £1,500 by £75 to £1,950 per annum, with placement according to qualifications and experience, and with superannuation benefit and family allowance where applicable. Some research experience in genetics is essential, and preference will be given to candidates prepared to teach either cytology or classical segregational genetics. It is hoped the successful candidate could take up his appointment on October 1, 1963.

Further particulars may be obtained from the undersigned, with whom applications (six copies), giving the names of two referees, should be lodged not later than April 17, 1963.

CHARLES H. STEWART,
Secretary to the University.

ST. GEORGE'S HOSPITAL

LINCOLN

COUNTY MEDICAL PHYSICS DEPARTMENT

Applications are invited for a post of Assistant Physicist in the County Medical Physics Department. The successful applicant may be appointed either in the Senior or Basic grade, depending on qualifications and experience. For the Senior grade appointment, experience in Radiotherapy Physics or Isotope Technique will be necessary. There are good facilities for work with modern Radiotherapy equipment, Radioactive Isotopes and in general medical physics. The salary is according to the Whitley Council scale.

Applications, giving details of qualifications and experience, together with the names of two referees, should be addressed to the Secretary, St. George's Hospital, Lincoln, from whom further particulars can be obtained.
